When the phenomena of terrestrial magnetism were first somewhat accurately observed about three hundred years ago, the needle pointed here in England a little to the east of north; a few years later it pointed due north; then, until about the year 1820, it went to the west of north; and now it has come back towards the north. The dip has experienced corresponding variations. The dip was first discovered by the instrument maker, Robert Norman, an illustration, I may mention in passing, of the benefits which abstract science derives from practical applications—one of the most important fundamental discoveries of magnetism brought back to theory by an instrument maker who made mariner's compasses. Robert Norman, in balancing his compass cards, noticed that after they were magnetised one end dipped, and he examined the phemonenon and supported a needle about the centre of gravity, magnetised it, and discovered the dip. When the dip was first so discovered by Robert Norman it was less than it is now. The dip has gone on increasing, and is still increasing; but about 50 years ago the deviation from true north was greatest. Everything goes on as if the earth had a magnetic pole revolving from west to east round the true North Pole, at a distance of 20° from it. About three hundred years ago its azimuth from England was a little to the east of the north pole: then it came round, moving eastwards on the far side of the north pole, and round in a circle towards us on the left-hand side of the north pole, as looked to from England. That motion in a circle round the north pole has already been experienced within the period during which somewhat accurate measurements have been made—has been experienced to the extent of rather more than a quarter of the whole revolution; and we may expect that about 200 years from the present time the magnetic pole will be between England and the North Pole; so that the needle will thus point due north, and the dip be greater than it has been for 1,000 years, or will be for another. It is one of the greatest mysteries of science, a mystery which I might almost say is to myself a subject of daily contemplation—what can be the cause of this magnetism in the interior of the earth? Rigid magnetisation, like that of steel or the load-stone, has no quality in itself in virtue of which we can conceive it to migrate round in the magnetised bar. Electric currents afford the more favoured hypothesis; they are more mobile. If we can conceive electric currents at all, we may conceive them flitting about. But what sustains the electric currents? People sometimes say, heedlessly or ignorantly, that thermo-electricity does it. We have none of the elements of the problem of thermo-electricity in the state of underground temperature which could possibly explain, in accordance with any knowledge we have of thermo-electricity, how there could so be sustained currents round the earth. And if there were currents round the earth, regulated by some cause so as to give them a definite direction at one time, we are as far as ever from explaining how the channel of those currents could experience that great secular variation which we know it does. Thus we have merely a mystery. It would be rash to suggest even an explanation. I may say that one explanation has been suggested. It was suggested by the great astronomer, Halley, that there is a nucleus in the interior of the earth, and that the mystery is explained simply by a magnet not rigidly connected with the upper crust of the earth, but revolving round an axis differing from the axis of rotation of the outer crust, and exhibiting a gradual precessional motion independent of the precessional motion of the outer rigid crust. I merely say that has been suggested. I do not ask you to judge of the probability: I would not ask myself to judge of the probability of it. No other explanation has been suggested.

But now, I say, we look with hopefulness to the practical telegraphist for data towards a solution of this grand problem. The terrestrial magnet is subject, as a whole, to the grand secular variation which I have indicated. But, besides that, there are

annual variations and diurnal variations. Every day the needle varies from a few minutes on one side to a few minutes on the other side of its mean position, and at times there are much greater variations. What are called "magnetic storms" are of not very unfrequent occurrence. In a magnetic storm the needle will often fly twenty minutes, thirty minutes, a degree, or even as much as two or three degrees sometimes, from its proper position—if I may use that term—its proper position for the time; that is, the position which it might be expected to have at the time according to the statistics of previous observations. I speak of the needle in general. The ordinary observation of the horizontal needle shows these phenomena. So does observation on the dip of the needle. So does observation on the total intensity of the terrestrial magnetic force.

The three elements, deflection, dip, and total intensity, all vary every day with the ordinary diurnal variation, and irregularly with the magnetic storm. The magnetic storm is always associated with a visible phenomenon, which we call, habitually, electrical;—aurora borealis, and, no doubt, also aurora of the southern polar regions. We have the strongest possible reasons for believing that aurora consists of electric currents, like the electric phenomena presented by currents of electricity through what are called vacuum tubes, through the space occupied by vacuums of different qualities in the well-known vacuum tubes. Of course, the very expression, "vacuums of different qualities" is a contradiction in terms. It implies that there are small quantities of matter of different kinds left in those nearest approaches to a perfect vacuum which we can make.

Well now, it is known to you all that aurora borealis is properly comparable with the phenomena presented by vacuum tubes. The appearance of the light, the variations which it presents, and the magnetic accompaniments, are all confirmatory of this view, so that we may accept it as one of the truths of science. Well now—and here is a point upon which, I think, the practical telegraphist not only can, but will, before long give to abstract science data for judging—is the deflection of the needle a direct effect of the auroral current, or are the auroral current and the deflection of the needle common results of another cause?

With reference to this point, I must speak of underground currents. There again I have named a household word to every-one who has anything to do with the operation of working the electric telegraph, and not a very pleasing household word I must say. I am sure most practical telegraphers would rather never hear of earth currents again. Still we have got earth currents; let us make the best of them. They are always with us; let us see whether we cannot make something of them, since they have given us so much trouble. Now, if we could have simultaneous observations of the underground currents, of the three magnetic elements, and of the aurora, we should have a mass of evidence from which, I believe, without fail, we ought to be able to conclude an answer more or less definite to the question I have put. Are we to look in the regions external to our atmosphere for the cause of the underground currents, or are we to look under the earth for some unknown cause affecting terrestrial magnetism, and giving rise to an induction of those currents? The direction of the effects, if we can only observe those directions, will help us most materially to judge as to what answer should be given.

It is my desire to make a suggestion which may reach members of this society, and associates in distant parts of the world. I make it not merely to occupy a little time in an inaugural address, but with the most earnest desire and expectation that something may be done in the direction of my suggestion. I do not venture to say that something may come from my suggestion, because, perhaps, without any suggestion from me, the acute and intelligent operators whom our great submarine telegraph companies have spread far and wide over the earth, are fully alive to the importance of such observations as I am now speaking of. I would just briefly say that this kind of observation is what would be of value for the scientific problem—to observe the indication of an electrometer at each end of a telegraph line at any time, whether during a magnetic storm or not, and at any time of the night or day. If the line be worked with a condenser at each end, this observation can be made without in the slightest degree influencing, and therefore without in the slightest degree disturbing, the practical work throughout the line. Put on an electrometer in direct connection with the line, connect the outside of the electrometer with a proper earth connection, and it may be observed quite irrespectively of the signalling; when the signalling is done, as it very frequently is at submarine lines, with a condenser at each end. The scientific observation will be disturbed undoubtedly, and considerably disturbed by the sending of messages, but the disturbance is only transient, and in the very pause at the end of a word there will be a sufficiently near approach to steadiness in the potential at the end of a wire connected with the electrometer to allow a careful observer to estimate with practical accuracy the indication that he would have were there no working of the line going on at the time. A magnetic storm of considerable intensity does not stop the working, does indeed scarcely interfere with the working, of a submarine line in many instances when a condenser is used at each end.

Thus, observations, even when the line is working, may be made during magnetic storms, and again, during hours when the line is not working, if there are any, and even the very busiest lines have occasional hours of rest. Perhaps, then, however, the operators have no time or zeal left, or, rather, I am sure they have always zeal, but I am not sure that there is always time left, and it may be impossible for them to bear the strain longer than their office hours require them. But when there is an operator, or a superintendent, or a mechanic, or an extra operator who may have a little time on his hands, then, I say, any single observation or any series of observations that he can make on the electric potentials at one end of an insulated line will give valuable results. When arrangements can be made for simultaneous observations of the potentials by an electrometer at the two ends of the line, the results will be still more valuable.

And, lastly, I may just say that when an electrometer is not available, a galvanometer of very large resistance may be employed. This will not in the slightest degree interfere with the practical working any more than would an electrometer, nor will it be more difficult to get results of the scientific observations not overpoweringly disturbed by the practical working if a galvanometer is used than when an electrometer is available. The more resistance that can be put in between the cable and the earth in circuit with the galvanometer the better, and the sensibility of the galvanometer will still be found perhaps more than necessary. Then, instead of reducing it by a shunt, let steel magnets, giving a more powerful direction to the needle, be applied for adjusting it. The resistance in circuit with the galvanometer between cable-end and earth ought to be at least twenty-times the cable's copper-resistance to make the galvanometer observations as valuable as those to be had by electrometer.

I should speak also of the subject of atmospheric electricity. The electric telegraph brings this phenomenon into connection with terrestrial magnetism with earth currents, and through them with aurora borealis, in a manner for which observations made before the time of the electric telegraph, or without the aid of the electric telegraph, had not given us any data whatever. Scientific observations on terrestrial magnetism, and on the aurora, and on atmospheric electricity, had shown a connection between the aurora and terrestrial magnetism in the shape of the disturbances that I have alluded to at the time of magnetic storms; but no connection between magnetic storms and atmospheric electricity, thunderstorms, or generally the state of the weather—what is commonly called meteorology—has yet been discovered.

The one common link connecting these phenomena hitherto known to us is exhibited in the electric telegraph. A telegraphic line—an air line more particularly, but a submarine line also—shows us unusually great disturbances, not only when there are auroras and variations of terrestrial magnetism, but when the atmospheric electricity is in a disturbed state. That it should be so electricians here present will readily understand. They will understand when they consider the change of electrification of the earth's surface which a lightning discharge necessarily produces.

I fear I might occupy too much of your time, or else I would just like to say a word upon atmospheric electricity, and to call your attention to the quantitative relations which questions in connection with this subject bear to those of ordinary earth currents and the phenomena of terrestrial magnetism. In fair weather, the surface of the earth is always, in these countries at all events, found negatively electrified. Now the limitation to these countries that I have made suggests a point for the practical telegraphists all over the world. Let us know whether it is only in England, France, and Italy that in fine weather the earth's surface is negatively electrified.

The only case of exception on record to this statement is Prof. Piazzi Smyth's observations on the Peak of Teneriffe. There, during several months of perfectly fair weather, the surface of the mountain was, if the electric test applied was correct, positively electrified; but Prof. Piazzi Smyth has, I believe, pointed out that the observations must not be relied upon. The instrument, as he himself found, was not satisfactory. The science of observing the atmospheric electricity was then so much in its infancy that, though he went prepared with the best instrument, and the only existing rules for using it, there was a fatal doubt as to whether the electricity was positive or negative after all. But the fact that there has been such a doubt is important. Now I suppose there will be a telegraph to Teneriffe before long, and then I hope and trust some of the operators will find time to climb the Peak. I am sure that, even without an electric object, they will go up the Peak. Now they must go up the Peak with an electrometer in fine weather, and ascertain whether the earth is positively or negatively electrified. If they find that on one fine day it is negatively electrified, the result will be valuable to science; and if on several days it is found to be all day and all night negatively electrified, then there will be a very great accession to our knowledge regarding atmospheric electricity.

When I say the surface of the earth is negatively electrified, I make a statement which I believe was due originally to Peltier. The more common form of statement is that the air is positively electrified, but this form of statement is apt to be delusive. More than that, it is most delusive in many published treatises, both in books and encyclopædias upon the subject. I have in my mind one encyclopædia in which, in the article "Air, Electricity of," it is said that the electricity of the air is positive, and increases in rising from the ground. In the same encyclopædia, in the article "Electricity, Atmospheric," it is stated that the surface of the earth is negatively electrified, and that the air in contact with the earth, and for some height above the earth, is, in general, negatively electrified. I do not say too much, then, when I say that the statement that the air is positively electrified has been at all events a subject for ambiguous and contradictory propositions; in fact, what we know by direct observation is, that the surface of the earth is negatively electrified, and positive electrification of the air is merely inferential.

Suppose, for a moment, that there were no electricity whatever in the air—that the air were absolutely devoid of all electric manifestation, and that a charge of electricity were given to the whole earth. For this no great amount would be necessary. Such amounts as you deal with in your great submarine cables would, if given to the earth as a whole, produce a very considerable electrification of its whole surface. You all know the comparison between the electricity of one Atlantic cable—the electro-static capacity of one of the Atlantic cables—with the water round its gutta-percha for outer coating, and the earth and air with infinite space for its outer coating.* I do not remember the figures at this moment; in fact, I do not remember which is the greater. Well, now, if all space were non-conducting—and experiments on vacuum tubes seem rather to support the possibility of that being the correct view—if all space were non-conducting, our atmosphere being a non-conductor, and the rarer and rarer air above us being a non-conductor, and the so-called vacuous space, or the interplanetary space beyond that (which we cannot admit to be really vacuous) being a non-conductor also, then a charge could be given to the earth as a whole, if there were the other body to come and go away again, just as a charge could be given to a pith ball electrified in the air of this room. Then, I say, all the phenomena brought to light by atmospheric electrometers, which we observe on a fine day, would be observed just as they are. The ordinary observation of atmospheric electricity would give just the result that we obtain from it. The result that we obtain every day in observations on atmospheric electricity is precisely the same as if the earth were electrified negatively and the air had no electricity in it whatever.

Well, now I have asserted strongly that the lower regions of the air are negatively electrified. On what foundation is this assertion made? Simply by observation. It is a matter of fact; it is not a matter of speculation. I find that when air is drawn into a room from the outside, on a fine day, it is negatively electrified. I believe the same phenomena will be observed in this city as in the old buildings of the University of Glasgow, in the middle of a very densely-peopled and smoky part of Glasgow; and therefore I doubt not that when air is drawn into this room from the outside, and a water-dropping collector is placed in the centre of the room, or a few feet above the floor, and put in connection with a sufficiently delicate electrometer, it will indicate negative electrification. Take an electric machine; place a spirit lamp on its prime conductor; turn the machine for a time; take an umbrella, and agitate the air with it till the whole is well mixed up; and keep turning the machine, with the spirit-lamp burning on its prime conductor. Then apply your electric test, and you find the air positively electrified.

Again—Let two rooms, with a door and passage between them, be used for the experiment. First shut the door and open the window in your observing room. Then, whatever electric observations you may have been performing, after a short time you find indications of negative electrification of the air. Then, during all that time, let us suppose that an electric machine has been turned in the neighbouring room, and a spirit-lamp burning on its prime conductor. Keep turning the electric machine in the neighbouring room, with the spirit-lamp as before. Make no other difference but this—shut the window and open the door. I am supposing that there is a fire in your experimenting room. Then, when the window was open and the door closed, the fire drew its air from the window, and you got the air direct from without. Now shut the window and open the door into the next room, and gradually the electric manifestation changes. And here somebody may suggest that it is changed because of the opening of the door and the inductive effect from the passage. But I anticipate that criticism by saying that my observation has told me that the change takes place gradually. For a time after the door is opened and the window closed, the electrification of the air in your experimenting room continues negative, but it gradually becomes zero, and a little later becomes positive. It remains positive as long as you keep turning the electric machine in the other room and the door is open. If you stop turning the electric machine, then, after a considerable time, the manifestation changes once more to the negative; or if you shut the door and open the window the manifestation changes more rapidly to negative.

It is, then, proved beyond all doubt that the electricity which comes in at the windows of an ordinary room in town is ordinarily negative in fair weather. It is not always negative, however. I have found it positive on some days. In broken weather, rainy weather, and so on, it is sometimes positive and sometimes negative. Now, hitherto, there is no proof of positive electricity in the air at all in fine weather; but we have grounds for inferring that probably there is positive electricity in the upper regions of the air. To answer that question the direct manner is to go up in a balloon, but that takes us beyond telegraphic regions, and therefore I must say nothing on that point. But I do say that superintendents and telegraph operators in various stations might sometimes make observations; and I do hope that the companies will so arrange their work, and provide such means for their spending their spare time, that each telegraph-station may be a sub-section of the Society of Telegraph Engineers, and may be able to have meetings, and make experiments, and put their forces together to endeavour to arrive at the truth. If telegraph operators would repeat such experiments in various parts of the world, they would give us most valuable information.

And we may hope that besides definite information regarding atmospheric electricity, in which we are at present so very deficient, we shall also get towards that great mystery of nature—the explanation of terrestrial magnetism and its associated phenomena,—the grand secular variation of magnetism, the magnetic storms, and the aurora borealis.

* The earth's radius is about 630 million centimetres, and its electrostatic capacity is therefore 630 microfarads, or about that of 1,600 miles of cable.

NOTES

We have frequently had occasion to refer to the energy and work of the Perthshire Society of Natural Science, and we rejoice to see that at its last meeting it has shown an example which we hope will be followed sooner or later by all scientific societies; it has resolved to make its influence felt in parliamentary elections. On the motion of the secretary, Dr. White, the following resolution was unanimously adopted:—"That in respect that Britain is apparently rapidly losing that commercial and

manufacturing supremacy which has heretofore distinguished her, and that it is high time that the Government of this country should take steps to retain that supremacy, and that means towards that desirable end is the appointment of a *responsible Minister of Education* whose duty it will be to see that our education machinery in all departments, both in extent and in efficiency, is kept up to the wants of the age, and that a thorough general education in the scientific principles on which the arts are founded (and without which training mere technical schools are of no use), is put within the reach of all, this society resolves that the candidates for the representation in Parliament of the County and City of Perth be respectfully requested to state, whether, in the event of their being elected they will use their influence to urge upon the Government; (1) the appointment of such responsible Minister of Education; (2) the promotion of scientific exploration expeditions, such as that of an Arctic expedition which the late Government was in vain requested to promote; (3) the providing of means for carrying on unremunerative scientific research." The secretary was accordingly directed to communicate with the candidates.

THE post of Hydrographer to the Navy has been bestowed by Mr. Goschen on Capt. J. O. Evans, R.N., C.B., F.R.S., in succession to Rear-Admiral Richards, C.B., F.R.S., who has retired.

THE first four wranglers on this year's Cambridge Mathematical Tripos, are, George C. Calliphronas, of Gonville and Caius College; Walter W. R. Ball, of Trinity College; James R. Harris, of Clare College; and Andrew Craik, of Emmanuel College.

THE following lectures in Natural Science will be given at Trinity, St. John's, and Sidney Sussex Colleges, during Lent Term, 1874:—On Sound and Light (for the Natural Sciences Tripos), by Mr. Trotter, Trinity College, in Lecture-room No. 11 (Monday, Wednesday, Friday, at 11, commencing Wednesday, Feb. 4); On Electricity and Magnetism (for the first part of the Natural Sciences Tripos and the special examination for the Ordinary Degree), by Mr. Trotter, Trinity College, in Lecture Room No. 11 (Tuesday, Thursday, Saturday, at 11, commencing Thursday, Feb. 5); On Inorganic Chemistry, by Mr. Main, St. John's College (Tuesday, Thursday, Saturday, at 12, in St. John's College Laboratory, commencing Thursday, January 29). Attendance on these lectures is recognised by the University for the certificate required by medical students previous to admission for the first examination for the degree of M.B. Instruction in practical chemistry will also be given. On Palæontology (the Annuloida, &c.), by Mr. Bonney, St. John's College (Tuesdays and Thursdays, at 9, commencing Tuesday, February 3). On Geology (for the Natural Sciences Tripos, Physical Geology), by Mr. Bonney, St. John's College (Mondays, Wednesdays, and Fridays, at 10, commencing Wednesday, February 4). Lithology: demonstrations with the microscope every Saturday at 11, commencing February 7. The class will be limited to six, and preference gived to members of the above colleges. Elementary Geology (for the First Part of the Tripos and the special examination) (Tuesdays and Thursdays, at 11. commencing Thursday, February 5). On Botany, for the Natural Sciences Tripos, by Mr. Hicks, Sidney College (Tuesday, Thursday, Saturday, at 11, in Lecture-room No. 1, beginning on Tuesday, February 3). The lectures during this term will be on Vegetable Histology and Physiology. A Course of Practical Physiol gy, by the Trinity Prælector in Physiology (Dr. Michael Foster) at the new museums. Lectures on Tuesday, Thursday, Saturday, at 12, commencing Tuesday, January, 27. This course is a continuation of that given last term.

DR. SCHMIDT, Professor of Astronomy in the University of Athens, has just completed his great map of the Moon. It is *two metres* in diameter, and is a marvel of accurate mapping and minute draughtmanship. The shading is so exquisite that any part of the map may be examined by a lens without the appearance of coarse or rough work. The map represents the labour of thirty-four years. and is without doubt one of the greatest astronomical results of the century.

THE discourse at the Royal Institution on Friday next, Feb. 6, at 9 P.M., will be by Mr. A. H. Garrod, Fellow of St. John's College, Cambridge, "On the Heart and the Sphygmograph."

A MARINE and Fresh-water Aquarium is to be established in the Central Park, New York, in connection with the Free Museum and Menagerie already erected there; it will be placed under the superintendence of Mr. W. Saville Kent, F.Z.S., who was, until a short time ago, Curator of the Brighton Aquarium. It is intended to raise the requisite funds by public subscription, and we are very pleased to be able to add that it is proposed to endow the Institution, so that it may be made available for the purposes of scientific research.

A PROJECT is on foot for the erection of a public aquarium at Liverpool, and a Company has been formed for this purpose; a suitable site has been secured close to the Philharmonic Hall, and operations will, we believe, be commenced at once. It is estimated the building will cost about 45,000*l.*

THE exhibition of appliances for the economic consumption of coal, which has been formed in the Peel Park, Salford, by the Society for Promoting Scientific Industry, was formally opened on Friday. Mr. J. Lowthian Bell, who had been announced to open the Exhibition, was prevented from being present, but forwarded the copy of an address which he had intended to deliver. This was read by the secretary, Mr. Larkins. The Exhibition will remain open for some weeks, and wil doubtless receive its share of public notice when the elections are occupying less attention than they are at present.

WE learn from the *Athenæum* that the Trustees of the British Museum have agreed to resign their patronage into the hands of the Government.

AN interesting peculiarity in the habits of some Indian Siluroid fishes has been noticed at a recent meeting of the Zoological Society by Surgeon F. Day, which will be described in full in the forthcoming Part of the Proceedings of that Society. Mr. Day, when fishing at Cassegode, found that, after having caught a large number of specimens of various species of *Arius* and *Osteogeniosus*, there were several siluroid eggs at the bottom of the boats, and in the fish-baskets. These eggs were, on an average, half-an-inch in diameter; and on looking into the mouths of several of the males of both genera, from fifteen to twenty eggs were seen in each; those in the boats and baskets having evidently dropped out from a similar situation. The eggs were in different stages of development, some advanced so far as to be just hatched. They filled the mouth, extending as far back as the branchiæ. No food was found in the alimentary canal, though in the females it was full of nutriment.

IN a paper on the Meteors of January 2, read before the American Philosophical Society, by Prof. Daniel Kirkwood, the author states, founding on data extending from A.D. 849 to 1864, that the meteors of this group have probably a period of thirteen years; that the mean distance is 5 53, aphelion 10.06; and that the source of the meteors may be the fourth comet of 1860, which in its ascending node approaches very near the point passed by the earth about January 3. If the period be thirteen years, the comet should have returned in the latter part of 1873, and the maximum fall of the associated meteors should occur about 1877.

Two legacies have recently been left to the French Academy of Sciences for the purpose of founding prizes. The one, a perpetual legacy of 2,500 francs, has been bequeathed by the late M. Gay, to be awarded as a prize in physical geography; and the other, a sum of 10,000 francs, the interest of which is to be awarded to the author of an astronomical work.

A GENTLEMAN in Glasgow who does not wish his name to be given, has just made a donation to Glasgow University of 1000*l*., for the better endowment of the chairs of astronomy, botany, and natural history.

AT the meeting of the Academy of Sciences at Paris on Monday, January 26, the place in the section of Anatomy and Zoology, vacant by the death of M. Coste, was filled up. M. P. Gervais was elected, but M. Alph. Milne-Edwards was a good second, obtaining 24 votes to M. Gervais's 33.

A NEW work by Mr. F. W. Burbidge, on "Cool Orchids, and how to grow them," is announced by Mr. Hardwicke, Piccadilly. It will be illustrated by coloured plates and wood engravings, and will be furnished with a copious list, in the shape of an index, of what are termed cool Orchids.

IN a despatch from Mr. Williams, H.M.'s Consul at Samoa, to the Foreign Secretary, dated Sydney, Oct. 28, 1873, it is stated that gold in quartz has been found in a valley in that island, about three miles from the Port of Apia; the samples assayed yielded at the rate of 3000 ozs. to the ton.

MR. J. F. GARDNER, geographer to Prof. Hayden's survey, in giving a short sketch of the method adopted by him to determine the altitude of the various points occupied by the party in the Rocky Mountains, states that the experience of the surveys of California and of the fortieth parallel show that in the determination of the altitude of any point a mercurial barometer is liable to an error varying from 150 to 300 feet, even when the base barometer is at the foot of the peak, and only 3000 feet below the summit. In connection with Professor Whitney (chief of the California Survey), the following plan was adopted for correcting the errors of barometrical work. Four points were chosen at successive levels of from one to 14,000 feet. These stations were carefully connected by levellings with a spirit level, and were occupied as permanent meteorological stations. The observations taken by field parties are classified according to their heights, and each class is referred to the base station which is nearest its own elevation; the lower station being Denver, the fourth the summit of Mount Lincoln (14,000 feet), where are a number of silver mines worked by Captain Breese. The central position of this peak admirably fits it for the base of reference. Besides the barometric determination of heights, two connected systems of trigonometric levelling have been carried over the whole area surveyed, and the check observations are so arranged that the probable error can be easily determined, and it is hoped that the system will prove accurate enough to throw some light on the amount of refraction at great elevations. By these methods the altitudes of many high points have been determined, from which to construct a map in contours 200 vertical feet apart, on a scale of two miles to one inch.

SIGNALLING between the earth and the planet Venus is a suggestion made in all good faith by a French astronomer, M. Charles Cros, who considers the coming transit of Venus to be a good opportunity for ascertaining whether there are inhabitants on that planet, and, if so, entering into relations with them. He says: "It is possible that Venus is inhabited; that amongst its inhabitants are astronomers; that the latter judge the passage of their planet across the solar disc to be an object to excite our curiosity; finally it is possible that these *savants* will strive in some way to make signals to us at the precise moment when they might suppose that many telescopes will be levelled at their planet."

IN a recent communication to the Connecticut Academy of Arts and Sciences, Prof. Marsh gave a statement of the results of his recent expedition to the Far West in search of fossil remains of extinct vertebrates. He said the richest field for exploration was found in the great basin of the pre-historic lake which is now drained by the Colorado River. This body of water was originally as large as all the present lakes of the North-West combined, and had existed so long that the sand washed down from the surrounding hills had accumulated to the depth of a mile. In the different strata of this bed at least ten distinct groups of extinct animals could be detected, among them some extremely remarkable forms. One of these was a rhinoceros with two horns; but these, not like those of the modern rhinoceros, in the axis of the body, but transversely. In a space of 10 ft. square he had sometimes found the bones of 30 different animals. The number of species of extinct mammals in these remains he estimates to be three times as great as that at present inhabiting the same locality.

A PAPER on Electrical Warfare will be read by Mr. Nath. J. Holmes, at the Society of Telegraph Engineers, on Wednesday, the 11th inst.

THE new Holmes' Shipwreck Distress Signal, of great power, will be exhibited from Primrose Hill on Thursday evening, 12th, at 8.30, in presence of the Marine Secretary of the Board of Trade. This signal is self-igniting in water, and inextinguishable.

THE Naples correspondent of the *Times*, writing on Jan. 25, states that Prof. Palmieri has just published the following letter in answer to the numerous applications sent to him for information:—"The activity of Vesuvius continues to increase in the crater towards the N.E. Frequent globes of smoke issue from the bottom of it, with a kind of hissing sound, accompanied by an unpleasant odour of chloridic and sulphuric acids. Not far from it, at the commencement of the grand fissure of 1872, alkaline sublimates make their appearance. Meanwhile the fire does not yet show greater activity at the bottom of the crater, where it will probably manifest itself, unless some eccentric eruption should occur before the internal resistance of this crater is overcome. The great subterranean energy now at work does, indeed, appear to be making an attempt at an outlet in various parts. On the 21st inst. a slight undulatory shock of earthquake was felt at Casamicciola, in the island of Ischia, and during the last week many have heard the low continuous mutterings of the mountain at a distance of 15 miles. As I write, however, the sismograph, which has been very agitated for some days, is more quiet." He also reports the melancholy death at Casamicciola of Mr. Moggridge, who having bathed in the open sea, died on his road to the hotel.

WE have received the Report of the *Senckenbergische naturforschende Gesellschaft* for 1872-73, a society of long standing, and with several eminent names in its list of members. The membership, we are glad to learn, shows a considerable increase during the year; though M. v. Fritsch states, in his report, that the efforts of the society are sadly hampered for lack of funds, and that "we exist and vegetate, rather than live." He laments, also, that the museum, which once stood fifth in importance in Europe, is being quickly surpassed by other like institutions, and thrown into the background; which is hardly creditable to a city of such wealth and culture as Frankfort. Among the researches detailed in this *Bericht*, we note a paper by Dr. Koch on the Arachnida of North Africa, especially those (hitherto unstudied) of the Atlas region, and the coast of Morocco; the

material having been collected by Drs. von Fritsch and Rein. The new types are not very numerous, but the remarkably wide distribution of spider-species is confirmed; and good illustration afforded of the influence of climate and other local conditions in modifying type forms. Dr. Rein describes some plants found in the neighbourhood of Mogador, and also furnishes a sketch of the vegetation of the Bermudas. A new species of perforating cirripede, *Kochlorine hamata* N., is described by Dr. Knoll; M. Scheidel contributes a note on lake dwellings and their inhabitants; and there are interesting accounts of journeys to Iceland, and to the Puglia Petrosa, in Italy.

WE have received the first Annual Report of the "Haileybury Natural Science Society." It contains preliminary lists of the fauna and flora of the place, together with observations on the meteorology of the locality, and a humorous description of an experimental dinner at which the principal dish consisted of esculent snails which had been specially fed and fattened for the purpose by certain members of the Society. It need scarcely be added, that the repast amply rewarded the members for their generous devotion to the cause of Science.

THE additions to the Zoological Society's Gardens during the past week include three Mauge's Dasyures (*Dasyurus maugæi*) from Australia, presented by Mr. J. Shaw; two Vulturine Guinea Fowl (*Numida vulturina*) from East Africa, presented by Dr. J. Kirk; a Chilian Sea-Eagle (*Geranoaëtus aguia*) from Bahia, presented by Mr. J. Judge; an Indian Leopard (*Felis pardus*) presented by Mr. G. D. Elphinstone; two Orang Outangs (*Simia satyrus*) from Borneo, and a Ungko Gibbon (*Hylobates variegatus*) from Sumatra, deposited; two Wanderoo Monkeys (*Macacus silenus*) from the Malabar Coast; a Brown Monkey (*Macacus brunneus*) and two Adjutants (*Leptoptilus argala*) from India, two Pheasant-tailed Pigeons (*Macropygia phasianella*) from N.S. Wales, and two Jambu Fruit Pigeons (*Ptilonopus jambu*) from the Indian Archipelago, purchased.

SCIENTIFIC SERIALS

American Journal of Science and Arts, December 1873.—In a paper on the magnetic permeability (that is "conductivity," according to Faraday), and the maximum of magnetism of iron, steel, and nickel, by Mr. Henry Rowland, C.E., the results are expressed, and the reasoning is carried out in the language of Faraday's lines of magnetic force. The quantity introduced, in mathematical theories of induced magnetisation, depending on the magnetic properties of the substance, is in these treated as a constant; but it was shown, in twelve cases of iron and two of nickel, to vary between wide limits. The author finds that the magnetisation of good iron can never exceed 175,000 times the unit magnetic field (on the metre, gramme, second, system), nor can nickel exceed 63,000 times; and from these data, and with aid of a formula of Prof. Maxwell's for tension of lines of force, it is inferred that the greatest weight which can be sustained by an electro-magnet with an infinite current, is, for iron, 354 lbs. per square inch of section, and for nickel 46 lbs. The results of experiment closely agreed with this.—Prof. Henry Draper communicates a note on diffraction-spectrum photography, accompanied with a photograph printed by the Alberttype process. (See NATURE, vol. ix. p. 223.)—We note several geological papers, one of them, by Prof. Fontaine, describing a remarkable deposit of bituminous matter, termed Grahamite, in Ritchie County, West Virginia, chemically resembling the mineral Albertite of New Brunswick, but differing considerably from this in its geological relations.—The age of the Lignitic formation of the Rocky Mountain region is far from decided, owing to the contrary evidence afforded by fossil plants and animals; and the editors propose to cite the arguments from various sources, in order, if possible, to bring about agreement. They give in this number the conclusions of M. Lesquereux from fossil plants. He refers the Lignitic beds to the Upper and Lower Eocene; and he gives a number of facts showing the disconnection of American Eocene flora from that of the Cretaceous, indicating truly separate formations.—Mr. Comstock describes the geology of Western Wyoming.—Mr. Verrill communicates the results of a recent dredging expedition on the coast of New England. It was ascertained that the body of cold bottom water approaches so nearly to the Coast of Maine as to manifest itself distinctly within twelve or fifteen miles of Cape Elizabeth, both by its highly Arctic fauna, and its icy temperature, even in summer.—In a letter from Cordoba, dated Sept. 8, 1873, Dr. Gould describes a remarkable swarm of locusts then occurring.

Astronomische Nachrichten, No. 1970, Jan. 14, contains the following papers:—On the determination of longitude by star-occultation and the telegraphically determined longitude between Madras, Singapore, and Batavia, by Dr. Oudemans. The author mentions his observations in 1859 as giving a longitude for Batavia of 7h. 7m. 12·5 s., also others in later years giving rather a less result. In 1870-71, however, the telegraphic communication with Singapore was used, giving a mean result of 11m. 40·895 s. longitude from that place. The same author gives a note on Kaiser's original proof of Foucault's pendulum researches. The proof is given by Prof. Oudemans, by which the plane of motion of the pendulum moves in azimuth in 1 sec., $15''. \sin \phi$. It is too long to give in full here, but appears simple and good. Prof. Oudemans has also two other papers on position observation made during the eclipse of Dec. 1871 at Java, and on the Spheroidal form of the earth, which consist chiefly of equations and tables which we have not space to introduce.—Dr. Holetschek gives ephemerides of a number of the minor planets.

Der Naturforscher, December 1873.—This number contains notes from the Bothkamp Observatory. In one of them M. Vogel gives observations of the spectra of several fixed stars, comparing the results obtained by Huggins and Miller. Another treats of periodic changes in the atmosphere of Jupiter. The observation that the occurrence of certain coloured stripes in Jupiter, and of bright egg-shaped spots in his equatorial zone coincided with the maximum epoch of sunspots, appears to be confirmed by a number of fresh data collected by the writer, Dr. Lohse. A third note describes observations of Venus in 1871-73, by M. Vogel, who thinks it probable that the planet is surrounded with an atmosphere in which floats a thick and dense layer of condensation products, so that little insight is afforded to the planet's surface, and the observation of spots helps but little to ascertaining the time of rotation or the position of the axis of rotation.—In physics, we have a note on the curious fact which M. Budde has recently studied, viz., that chlorine, when acted on by very refrangible rays of light, undergoes expansion and heating. Some experiments, made by M. Hirn, on the optical properties of flame, tend to show that flame is not perfectly transparent to light (as Arago and M. Offret have affirmed), but that particles in the glowing state are; the weakening of light in its transmission through flames is due to the various refractions it undergoes, and consequent dispersion. The author is led to some speculations on the sun's temperature, and he puts the case thus: If the glowing parts of the photosphere are intransparent, the temperature must (according to mathematical calculation), be nearly six million degrees; if they are transparent, it must be considerably less; and the lower, the greater the transparency. The problem is one for experimental physics, the question being, Are all solid or liquid bodies transparent and diathermanous when brought to a very high temperature? M. Hirn, we have seen, inclines to reply in the affirmative. We find accounts of Prof. Guthrie's discovery of a new relation between heat and electricity, and M. Herwig's experiments on pulverisation of electrodes in the voltaic arch.—Chemistry is represented by papers on the laws governing water of crystallisation, and the reduction of carbonic acid by phosphate of iron.—The action of camphor on plant life has been recently studied by M. Vogel at Munich, in a series of experiments which confirm an almost forgotten observation by Barton in the last century, that camphor has a stimulant effect on plants analogous to that of spirituous liquors or opium, in certain quantity, on the human system. There are also botanical notes on the influence of CO_2 on verdant growth of plants (M. Böhm), and on the geographical distribution of the Cupuliferæ (M. Oersted); and, in technology, M. Riche discusses the physical properties of certain alloys.

SOCIETIES AND ACADEMIES

London

Geological Society, Jan. 21.—Prof. P. Martin Duncan, F.R.S., vice-president, in the chair.—"The secondary rocks of Scotland (second paper). On the ancient volcanoes of the Highlands and their relations to the Mesozoic strata," by J. W. Judd, F.G.S. That the rocks forming the great plateaux of the Hebrides and the north of Ireland are really the vestiges of innumerable lava-streams, is a fact which has long been recognised by geologists. That these lavas were of *subaerial* and not *subaqueous* origin is proved by the absence of all contemporaneous interbedded sedimentary rocks, by the evidently terrestrial origin of the surfaces on which they lie, and by the intercalation among them of old soils, forests, mud-streams, river-gravels, lake deposits, and masses of unstratified tuffs and ashes. From the analogy of existing volcanic districts, we can scarcely doubt that these great accumulations of igneous products, which must originally have covered many thousands of square miles, and which still often exhibit a thickness of 2,000 ft., were ejected from great volcanic mountains; and a careful study of the district fully confirms this conclusion, enabling us, indeed, to determine the sites of these old volcanoes, to estimate their dimensions, to investigate their internal structure, and to trace the history of their formation. The following is Mr. Judd's conclusion on the subject of his paper:—It appears that during the Newer Palæozoic and the Tertiary periods, the north-western parts of the British archipelago were the scene of displays of volcanic activity upon the grandest scale. During either of these, the eruption of felspathic lavas, &c., preceded, as a whole, that of the basaltic; and in both the volcanic action was brought to a close by the formation of "puys." The range of Newer-Palæozoic volcanoes arose along a line striking N.E. and S.W.; that of the Tertiary volcanoes along one striking from N. to S.; and each appears to have been connected with a great system of subterranean disturbance. It is an interesting circumstance that the epochs of maximum volcanic activity, the Old Red sandstone and the Miocene, appear to have been coincident with those which, as shown by Prof. Ramsay, were characterised by the greatest extent of continental land in the area. The Secondary strata were deposited in the interval between the two epochs of volcanic activity, and the features which they present have been largely influenced by this circumstance. Apart from this consideration, however, the volcanic rocks of the Highlands are of the highest interest to the geologist, both from their enabling him to decipher to so great an extent the "geological records" of the district, and from the light which they throw upon some of the obscurest problems of physical geology.—Remarks on fossils from Oberburg, Styria, by A. W. Waters, F.G.S. The author noticed the limited occurrence of Eocene deposits in Styria, and referred briefly to the researches of Prof. Reuss and Prof. Stur upon them. He then indicated certain species of fossils which he had detected in these beds, adding about nine species to Stur's list.

Anthropological Institute, Jan. 27.—Prof. Busk, F.R.S., president, in the chair.—Aniversary Meeting.—Before proceeding to read his address, the president referred to the financial condition of the Institute, which, although it showed that the receipts were adequate for the necessary expenditure on the present economical principles of management, would not admit either of paying off any more of the debt or of increasing the scope and usefulness of the Institute. Until the unfortunate and utterly indefensible secession of members early in 1873, on a purely personal question, the Institute, since its formation, had paid off the combined debts of the two old societies at the rate of 100*l.* a year. He appealed to the loyalty of the members now forming the Institute to make a united effort finally to extinguish the debt of 800*l.* A year's income would do it, and it was suggested that if each member contributed one year's subscription, that great result would be attained and the Institute would certainly before long occupy a high position amongst the scientific bodies of the kingdom. As an encouragement to the body of members and as an earnest of the sincerity and vigour of his colleagues in management, the president had much pleasure in announcing that nearly 250*l.* had been promised by members present at a council-meeting held that day, provided the sum of 500*l.* be contributed by other members of the Institute.—The president then delivered the annual address, in which he viewed the work done during 1873 by English and foreign anthropologists. Amongst a large number of topics he adverted at considerable length to the important contributions to craniometry, by Dr. H. von Jhering and Dr. Paul Broca, criticising the respective methods employed by those distinguished anthropologists; and concluded that part of his address with the observation that the study of craniology is almost futile when applied to highly civilised, and consequently much mixed peoples, and that its results are the more certain in proportion to the purity of race. That purity at the present time was rapidly disappearing, and with it the surest data for the determination of the problems involved in the antiquity and physical origin of man.—The following was the list of officers and council elected to serve for 1874:—President—Prof. Geo. Busk, F.R.S. Vice-presidents—John Evans, F.R.S.; Col. A. Lane Fox, F.S.A.; A. W. Franks, M.A.; Francis Galton, F.R.S.; Prof. Huxley, F.R.S.; Sir John Lubbock, Bart., F.R.S. Director—E. W. Brabrook, F.S.A.—Treasurer—Rev. Dunbar I. Heath, M.A. Council—Dr. John Beddoe, F.R.S.; W. Blackmore; H. G. Bohn, F.R.G.S.; Dr. A. Campbell; Hyde Clarke; Dr. J. Barnard Davis, F.R.S.; W. Boyd Dawkins, F.R.S.; Robert Dunn, F.R.C.S.; David Forbes, F.R.S.; Sir Duncan Gibb, Bart, M.D.; George Harris, F.S.A.; J. Park Harrison, M.A. J. F. McLennan; C. R. Markham, C.B. F.R.S.; Frederic Ouvry, F.S.A.; F. G. H. Price, F.R.G.S.; J. E. Price, F.S.A.; F. W. Rudler, F.G.S.; C. R. Des Ruffières, F.R.S.L.; E. Burnet Tylor, F.R.S.

Edinburgh

Royal Physical Society, Jan 28.—Mr. Scot Skirving, president, in the chair.—The following communications were read: Note on the Crushed Boulders from the Old Red Conglomerate in Kincardineshire, by James C. Howden, M.D., —On Crushed Boulders from Arbroath, and other localities, by Mr. Charles W. Peach.—Report of the Dredging Committee for 1873, by James Middleton, M.B., convener. The meeting of the committee had been held conjointly with the Naturalists' Field Club. In all about 133 species of animals had been obtained, including two new to the Firth of Forth.—Note on the Suspension of Clay in Water, by Mr. William Durham. This research was undertaken in continuance of those recorded in the papers on the same subject read at the last meeting. As the general result of Mr. Durham's elaborate and careful series of experiments, it was found that clay held in suspension by water sinks more quickly if the water is slightly acidulated, and more slowly if a slight amount of an alkali is added, but that the conditions are reversed if a large amount of either substance is mixed with the water.

Manchester

Geological Society, Jan. 27.—Mr. J. Dickenson Hill in the chair.—Mr. J. Aitken exhibited some new fossil fishes from the millstone grit, Yorkshire, and read a paper descriptive of the bed whence they were obtained. He said that evidences of fossils had been brought to the surface during the excavations connected with the scheme for taking water from Widdop colliery to the borough of Halifax by a tunnel cut through Wadsworth Moor, about two miles north of Hebdenbridge. After an examination, by no means exhaustive, there had been discovered seven specimens of *Goniatites*, three of *Nautili*, two of *Orthoceratites*, two of *Avicula pecten*, two of *Posodonia*, one of *Gastropod*, one of *Milamia*, fish remains, &c. The discovery of the most remarkable character was a new species of *Acrolepis* presenting peculiar characteristics. The situation in which these remains occurred was near but somewhat above the middle of the shells which usually divided the third floors from the fourth or undermost grit.

Göttingen

Royal Academy of Sciences, Nov. 1, 1873.—M. Schering communicated a paper on the Hamilton-Jacobi theory for forces whose measurement depends on the motion of bodies.—MM. Wagner, Philippi, and Tollens described some researches on the Allyl group, made with the view of establishing the constitution of allyl alcohol, and of some of its compounds, especially acrylic acid. They find new evidence, in opposition to Wislicenus, that acrylic acid, as well as acetic acid, propionic acid, and all other organic acids, contains the group CO_2H, and may therefore be classed with them.—MM. von Grote and Tollens described an acid obtained from cane sugar by means of dilute sulphuric acid; and M. Tollens gave the first results of an investigation as to combinations of starch with alkali.

Nov. 20.—Prof. Lüroth read a paper on reckoning by projections; and Prof. Hattendorff made some observations on Sturm's theorem.

Dec. 3.—M. Enneper communicated a paper on the general theory of surfaces.

Dec. 10.—The Society celebrated its 121st anniversary. The prizes for competition in the next three years were announced. In the physical section the Society invites experiments on the artificial production of some crystallised minerals, as stephanite, pyrargyrite, grey copper ore, galena, fluor spar; in order to solution of the question how crystallised sulphur and fluor-compounds have arisen in the natural state. In the mathematical section, the Society desires an investigation of current-work, *i.e.* the work done by the electro-motive forces in their action on the current electricity, especially in its relation to the heat produced from the current, and the *vis viva* produced from it immediately in the current electricty, or mediately, in other movable particles in the conductor. Papers on these subjects must be sent before Sept. 1875, in the former case, and Sept. 1876, in the latter. The prizes offered are fifty ducats each.—Prof. Ewald communicated an interesting paper on the so-called rhetorical ornaments of Oriental speech (a subject suggested, apparently, by the late visit of the "king of kings)."—M. Riecke presented a note on the function of leaf-teeth, and the morphological value of some leaf-nectaries. In the bud, the teeth often prevent the hermetical closure of the two folded halves of the leaf; which is perhaps important, that the bud may not suffer from the want of gas. A more evident function consists in the separation of resin or mucilage. *Prunus avium* is taken as a good example; and two other types of structure are also described. The teeth of leaves of *Prunus avium* are closely allied, morphologically, to numerous nectar-secreting organs in these and other kinds of leaf.

Dec. 17.—M. Bjerknes read a paper giving a generalisation of the problem of motions produced in a still inelastic fluid by the motion of an ellipsoid.—M. Wöhler presented a list of the meteorites in the University collection at Göttingen.

Vienna

Imperial Academy of Sciences, Dec. 4, 1873.—Prof. Mach stated that he had made experiments, during the summer, on the time required for rotation of the plane of polarisation by a current—a flint glass disc being rotated between the magnetic poles; but similar experiments by Villari had been described in *Pogg. Ann.* (No. 7, 1873), and the results were almost identical. Villari used a double plate; and Prof. Mach points out another very simple method for such researches, viz., the spectral observation of a sounding glass rod placed between the magnetic poles.—A paper by Dr. Dvorak described some experiments on the velocity of sound in gas-mixtures. If a mixture is made of two different gases, with densities d and d' respectively, and both with an expansive force 1, the velocity of sound V in the mixture $= \sqrt{\frac{2}{d + d'}}$. The author's results show close agreement with the theory. Thus for mixtures of carbonic acid and hydrogen, air and hydrogen, ordinary gas and CO_2, respectively, the observed and calculated numbers for the half wave-length of a given tone were these: 71·5, 71·0; 88, 89·0; 64, 63·3. The author remarks that for a simple gas, as well as for a mixture of gases, the gas theory implies not one velocity, but a graduated series of velocities, of sound; and perhaps the prolongation in sound of a cannon shot heard at a distance may be thus explained.—Dr. Exner communicated a determination of the temperature at which water has a maximum of density. He improved on Rumford's method by using thermo-elements instead of a mercury thermometer. The value obtained was 3·945°.

Paris

Academy of Sciences, Jan. 26.—M. Bertrand in the chair.—The following papers were read: On the various reactions of the compounds of oxygen and nitrogen, by M. Berthelot.—On the production of yeast in a mineral solution containing sugar, by M. Pasteur. The author described the growth of yeast in a solution of inorganic substances such as enter into the composition of its ash added to a solution of sugar. M. Trécul replied at some length to certain of M. Pasteur's remarks.—On the liquefaction and solidification of acetylene by the silent electric discharge, by MM. P. and A. Thenard. The author found that this gas condensed at the rate of four or five cubic centimetres a minute into a solid horny body isomeric with acetylene; by varying the conditions of experiment a liquid isomer was also obtained.—Experimental researches on Newton's rings, by M. P. Desains.—Direct demonstration of the equation $\int \frac{dQ}{T} = 0$ for every closed and reversible cycle, by M. A. Ledieu. This paper formed a sequel to the author's other papers on thermo-dynamics, lately published.—Note on Poncelet's teaching of applied mechanics, by General Morin.—A note from Prof. Nordenskiöld was read; he has detected iron, nickel and cobalt in the carbonaceous dust found in 1870 on the Greenland snow; traces of phosphorus were also found.—Instructions for M. Doûmet-Adanson's travel in Tunis, by M. Cosson. The instructions are issued to M. Adanson, who is about to undertake a botanical exploration of Tunis.—On magnetism, by M. J. M. Gaugain.—New researches on the rejoining end to end of the fibres of sensory with the fibres of motor-nerves, by M. A. Vulpian.—Organogenesis compared with androgenesis in its relation to natural affinities, by Ad. Chatin. This portion of the author's paper deals with the *polygonoïd* and *cactoid* plants.—Researches on the silicified plants of Autun; study of the genus *Myelopteris*, by M. B. Renault.—On the presence of a considerable proportion of potassic nitrate in two varieties of *Amaranthus*, by M. A. Boutin. The author found that *A. atropurpureus* contained 22·7 and *A. ruber* 16·0 per cent. of the weight of the dried plant; he suggested a possible future cultivation of the plant on this account.—On the theory of the flight of birds, by MM. H. and L. Planavergne.—On a statistical chart showing the distribution of the population of Paris, by M. Vauthier.—On the geometrical properties of rational fractions, by M. F. Lucas.—On the determination of the pluckerian numbers of envelopes, by M. H. G. Zeuthen.—On the theory of numerical equations, by M. Laguerre.—On the breaking of magnetised needles, by M. Bouty. The author found that if the steel was very brittle and broke like glass the two portions are magnets of the same magnetic moment, but not so if the steel has to be bent backwards and forwards before it breaks.—On certain peculiarities in the efflorescence of the two hydrates of sodic sulphate, by M. D. Gernez.—Researches on the reaction of argentic chloride on phosphoric di-iodide, by M. Arm. Guntier.—On the isomerism of terebenthene and terebene, from a physical point of view, by M. J. Ribau.—On the alterations of the soft matter (of the brain) accompanying the tearing and cutting back of the sciatic nerve in the rabbit, by M. G. Hayem.—On the pluvial *régime* of the torrid zones in the Indian and Pacific Ocean basins, by M. V. Raulin.—Note on Professor Tyndall's experiments on the acoustic transparency of air, by M. W. de Fonvielle.—On the production of crystals of calcic oxalate and ammonic-magnesic phosphate, by M. E. Monier. During the meeting, the Academy elected M. Gervais as successor to the late M. Coste, of the section of Anatomy and Zoology.

THURSDAY, FEBRUARY 12, 1874

A MINISTER FOR SCIENCE

WE are glad to see that the *Times* has at last opened its pages to the question of the propriety of appointing a responsible Minister, whose duty it shall be to look after the interests of Science and of scientific research and education, and take charge of the scientific institutions of the country—institutions whose efficiency is at present sadly crippled from the want of a single responsible head. The whole question could not be better stated than in Colonel Strange's letter which appeared in the *Times* of the 6th inst., and which we consider so admirably to the point, that we gladly reproduce it here. We hope the letter will lead to further discussion, and that whatever Government may hold the reins in the forthcoming Parliament, the important question now raised may meet with serious attention. Colonel Strange's communication runs as follows:—

"No subject affecting the material interests of England is more important at the present day than that discussed at Manchester by Lord Derby, and by yourself in your leader of the 12th ult.

"'Scientific industry' is one of those clever phrases calculated to catch the eye and ear by its novelty, while it expresses what is already well known by other antiquated names. Lord Derby defines it and explains its meaning in a variety of ways; but throughout his whole speech he is talking, while never naming it, of nothing more nor less than scientific research. The utilisation of redundant natural forces and of waste substances, on which he insists as a primary object of the new movement, is to be brought about by patient, continuous, systematic research, and by nothing else. I own I prefer the old words to the new, but if by using new words old wants come to be recognised and supplied, I shall not complain.

"I, and many who think with me, maintain that scientific research must be made a national business; that the point at which Science, in most of its leading branches, has now arrived and the problems presented for solution are such as to need for their adequate treatment, permanent well-equipped establishments with competent staffs worked continuously and systematically. Lord Derby truly describes it as a case in which what is 'everybody's business is nobody's business.' We must make it somebody's business. We must make it the State's business. We have tried individual enterprise, which so many hold to be all-sufficient. There is more individual enterprise in England than in any country in the world, and yet we are being rapidly outstripped by nations who, though they encourage private exertion, are wise enough not to rely on it, but to establish a system free from the caprice, the incompleteness, the liability to interruption and cessation incident to all individual labour in whatever field. If asked to describe the system we propose to establish, our reply is in one word, 'completeness.' A steam-engine is a system, composed of many parts, each and all essential to its useful action. Furnace, boiler, cylinder, pistons, connecting rods, beam, and fly-wheel—all controlled by a governor. Tested by the condition 'completeness,' what is Lord Derby's new society? What is any private society? A mere connecting rod—a most useful link in the system, not to be dispensed with, but still a mere link. Where are the other parts? Is there a trace of them in England?

"The first essential to any system is a head. No domestic household, no manufactory, no ship, no army or navy, no public or private establishment of any kind, and these are all 'systems,' can hold its own for a day without a head. But at the present hour there is no head to the science of England. The proposed remedy for this deficiency will have been anticipated as obviously a Minister of State, who shall be responsible to the nation through Parliament for everything connected with the scientific business of the country. For want of this head what have we done? The various scientific institutions at present maintained by the State are distributed according to the following list, which was correct some time since, but may have undergone recent changes:—1, Royal Observatory, Greenwich, under the Admiralty; 2, Royal Observatory, Edinburgh, under the Office of Works; 3, Royal Observatory, Cape of Good Hope, under the Colonial Office; 4, 5, 6, the Observatories at Madras, Calcutta, and Bombay, under the India Office; 7, Ordnance Survey of Great Britain, under the Office of Works; 8, the Great Trigonometrical Survey of India, under the India Office; 9, Exchequer Standards Office, under the Board of Trade; 10, the Royal School of Mines, under the Privy Council; 11, British Museum, under 50 irresponsible trustees; 12, Meteorological Office, governed by an unpaid, and therefore irresponsible, Committee of the Royal Society, under the Board of Trade; 13, the Royal Botanic Gardens of Kew, Edinburgh, and Dublin, under the Board of Works; 14, the Geological Survey, under the Privy Council. My list is perhaps not quite complete, but as it stands it shows that we place our scientific institutions under no less than seven different Departments of State, all of which have other matters besides science to attend to. Can anyone pretend there is any trace of a system here? Is it not a grotesque caricature of State administration?

"Granted that there must be a Minister for Science—and I am happy to say that those who have given most attention to the question now admit that there must—then the whole of the institutions I have named, besides some others now in existence, and many others that must before long be founded, would be placed under him. This would secure the great object of harmony and unity of parts, of provision for modification and extension, and of definite responsibility to the nation through Parliament, none of which objects are obtainable or seem even dreamt of at present.

"Whether such a Ministry should be created as additional to what we at present possess, or whether some existing Minister should be charged with Science; whether the Science Minister should not also take Education, Art, and Music under his care; whether he should not have permanent unparliamentary advisers, and if so on what scale and how constituted, besides many other points, are all extremely important questions, admitting of a great variety of answers; but compared with the fundamental necessity for a Minister at the head of a Department controlling the whole public scientific activity of the kingdom, they are matters of subordinate detail.

"The Royal Commission on Science, presided over by the Duke of Devonshire, has, for nearly three years, been most assiduously engaged in collecting a body of information of infinite value, and they will no doubt forward many important recommendations on the evidence they have taken; but for my part, as one deeply interested in their proceedings, to which I have contributed largely as a witness, I do not hesitate to say that if they only succeed in obtaining the creation of a Science Minister, that re ult alone will amply repay the country for the cost of their investigations.

"Let this be done, and we should cease to witness the farce of consulting the Chancellor of the Exchequer about observing eclipses of the sun, the Prime Minister about scientific Arctic expeditions, and the Treasury about tidal reductions. We should perhaps, too, then perceive that overworked Law Officers are not the best managers of a great, or what should be a great, technical Museum, and that fifty irresponsible gentlemen, however eminent individually, ought not to be entrusted with the grandest collection of Art and Natural History in the world. Nor would a wise statesman like Lord Derby fail to perceive, with all science concentrated under one view for his inspection, that a private local Society will prove no match for the complete and powerful State systems of Germany, France, and other Continental nations."

PINK AND WEBSTER'S "ANALYTICAL CHEMISTRY"

A Course of Analytical Chemistry (*Qualitative and Quantitative*). By William W. Pink and G. E. Webster. (London: Lockwood & Co., 1874.)

THIS work forms a volume of Weale's Rudimentary Series, and is advertised "as specially adapted for the use of those students who intend competing in the Advanced or Honours Stage Examinations (Inorganic Chemistry) of the Science and Art Department, also for preparing those intended to sit for the higher class examinations at Colleges, Public Schools," &c. The success which several well-known serial publications of a similarly special nature have deservedly had, appears to have stimulated the publishers of Weale's Series to embark in this enterprise. As the excellence of most of their former publications will be generally admitted, we can only regret that a literary (?) production displaying such deplorable ignorance should ever have found a place in their series. It has rarely been our duty to pass judgment on a more carelessly got-up book. Had it not been advertised as specially adapted for the use of the Science Classes under the Science and Art Department, we might have put it aside with a hearty laugh over the many absurd blunders it contains. Since a practice has, however, sprung up of late to cater for the wants of Science Classes, by printing books (sometimes obtained on commission) privately, and advertising them by means of post-cards, at so many postage stamps a copy, whereby these books manage to escape the eye of the reviewer, and as we fear that much mischief is being done by certain cheap cram-books, strung together with a view to save the teacher as much trouble as possible, our readers will perhaps bear with us if we examine the book before us somewhat closely. If rumour speaks true, some teachers manage to teach chemistry — even analytical chemistry—without ever touching a test-tube or performing the simplest experiments. Questions from previous examinations are eagerly collected and "worked" in the belief that the examiner is sure to give, if not the same questions, at least others of a similar nature. We need not fear giving offence to those earnest and hard-working men, engaged, often on a mere pittance and under most adverse and discouraging circumstances, in imparting a sound knowledge of chemistry in places which would not otherwise be reached by any educational efforts, if we conclude from the course of analytical chemistry before us, that some teachers (Mr. Webster styles himself Lecturer on Metallurgy and the Applied Sciences, Nottingham) are deplorably ignorant of the science they profess to teach.

Beginning on p. 4, we are told that "the term atom is sometimes applied to a compound as well as simple radicals, such as ammonia, hydroxyl, &c.": that "for fixed solids which do not vaporise, the atomic weights are referred to the element lithium, the atomic weight being determined by the amount of heat which any body contains, when it is at the same temperature as lithium, both being the same weight, lithium being considered as seven." On p. 7, "difference of attraction is called the bond affinity, that is, it is assumed that the different atoms possess power, lines of force, or *points of attraction*, called by Dr. Frankland *bonds*." On p. 12, we are informed, that "there are four different forms of notation, or formulæ in present use, two of which are *graphical*, viz. the *glyptic* and *graphic* formulæ. The other two, viz. the empirical and the constitutional or rational, are the symbolic representations." We give it upon the authority of our joint authors, that "Dr. Crum Brown was the first to introduce this form of formulæ, and that it has now been adopted by Dr. Frankland, and generally throughout the kingdom." And on p. 14, we are told, that "students who do not already understand the constitutional formulæ are strongly advised to obtain a complete knowledge of them, not only as an addition to their knowledge, but because the other is now not recognised by many colleges, or *allowed* in many examinations." For fear our authors' inadvertence should lead to further mischief, we may at once state that, to our knowledge, such is not the case, and that the authors are as much in the dark about what is recognised by many colleges or "allowed in many examinations" as they are about chemical analysis.

We can only pick out some of the choicest specimens from the authors' analytical bouquet. Beginning on p. 26, we are told that "deflagration is the arrangement of the crystals of a substance, and is, in ordinary terms, the crackling of a body when exposed to heat;" on p. 28, that "hardly any amount of reading or lecture-hearing can produce a practical analyst, as only practice can make perfect, and therefore the student is strongly recommended to make the experiments himself." We for once entirely agree with the theory, but strongly object to the "practice" of our joint authors. The information on p. 30, that "melted lead cannot be poured even in a cold platinum crucible without spoiling it, and that a drop of lead, tin, or bismuth, falling upon a red-hot platinum vessel invariably makes a hole in it," we owe probably to the sad experience gained by the metallurgical partner in the joint-authorship, and science-students possessing platinum

vessels must surely feel thankful for the hint. Great confusion of ideas seems to prevail, however, on the subject of platinum, for we are told on p. 31 that "platinum combines easily with silica and carbon, so that the contact of platinum crucibles with charcoal at a very high temperature must be avoided," together with several other absurd precautions which we will not quote. On p. 33, there figures an apparatus for rapid filtration in an atmosphere of steam, which we have seen before in Normandy's Introduction to his translation of Rose, and which we should have thought had been superseded long ago by more perfect methods of filtration.

As specimens of analytical knowledge (?) we quote p. 57, "hydrochloric acid gives a precipitate on dilution with water (distilled) if $BaCl_2$ or SO_2Ho_2 be present;" p. 38, "dilute sulphuric acid contains more lead, and lead is scarcely soluble in concentrated acid;" p. 42, "A solution of baric chloride must be neutral to test-paper, after precipitation by sulphuric acid;" p. 43, "sodic carbonate must completely volatilise;" p. 46, "hydrofluosilcic acid can be obtained from the chemists in india-rubber bottles."

The analytical tables on pp. 57 to 73 are equally deficient and faulty. We are told to test for ammonia, after having ignited on platinum foil; "a watch-glass becomes corroded on the addition of baric chloride to a neutral solution of salts," "hydrobromic acid turns starch-paper blue," "sodic hydrate," on p. 94, "precipitates light-coloured ferric hydrate which turns dirty-green." Upon heating chlorates, p. 115, "a very violent deflagration ensues." The authors appear never even to have prepared oxygen gas.

The quantitative knowledge displayed by the authors is quite on a par with the choice bits of qualitative chemical information so liberally and innocently volunteered by them. We will not tire our readers, however, by any further quotations, but cannot refrain from firing a parting shot or two by quoting from p. 120, where we are told that "Chlorine is prepared by the mixing of salt, hydrochloric acid and manganic oxide; this last, MnO_2, has no chemical reaction in the last equation;" and from p. 136, on which we are told that "in order to keep the edges of the balance free from rust, it is a very good practice to place inside the case a beaker, half-filled with sulphuric acid or baric chloride." A dialyser is described on p. 171 as "an apparatus having sides and top of gutta-percha, and bottom of parchment, and is used for the separation of urea and other crystallisable salts from urine."

Need we do more than recommend the authors to act upon their own advice (p. 2), and "to speedily endeavour to obtain a complete knowledge of the composition of bodies, and make themselves conversant with the formulæ &c.," of which they exhibit so deplorable an ignorance, before they again venture upon enlightening the public on the subject of chemistry.

THE RACES OF MANKIND

The Races of Mankind: being a Popular Description of the Characteristics, Manners, and Customs of the Principal Varieties of the Human Family. By Robert Brown, M.A., Ph.D., &c. (Cassell, Petter, and Galpin).

THE rapid growth of interest in Anthropology is proved by the appearance, one after another, of popular illustrated works: Mr. J. G. Wood's "Natural History of Man" in 1868-70, an English translation of M. Louis Figuier's "Human Race" in 1872, and just now (though without the date it ought to have on the title-page) this first volume of a work on "The Races of Mankind." Of these, the productive M. Figuier's book is too worthless to say much of, and the comparison lies between the first and last. Both are valuable, and the ground they cover is so far different, that they may be usefully placed side by side in the ethnologist's library. It will be remembered that Mr. Wood's account of Africa occupied the first of his two volumes, so that his account of the races of Asia, America, Polynesia, &c., had to be disproportionately condensed into the second. Dr. Brown, we trust, will be able to keep his scale more uniform. His first volume treats entirely of American races, and he speaks with personal knowledge of the Esquimaux and North-west tribes, compiling as to other tribes with discretion, and generally from not too hackneyed authorities. Such of Dr. Brown's illustrations as are taken from photographs and real drawings are good, and preferable to the too picturesque and imaginative cuts of Mr. Wood's artists. But Dr. Brown inserts some drawings which he had better for truth and good taste have left out. Thus, the Indian scalping his victim at page 68, though no doubt more like the reality than the engraving in vol. ii. of "Schoolcraft," from which it is a kind of rationalised copy, is a piece of sensational make-up; while on the next page a scene of Indians torturing a captive by a slow fire on his stomach, is still more objectionable. At page 284 is a representation of Conibos shooting turtle; this is evidently a fancy picture, and arrows shot at such an angle would glance off the animal's carapace; the arrows should have been shown of heavier make, and so sent up as to fall almost perpendicularly.

As only the first part of Dr. Brown's work is yet out, it may perhaps be a service to make some suggestions. Native words are sometimes wrongly printed, which gives an air of carelessness to the descriptions they form part of. Thus "inniut" instead of "innuit" (p. 5); "Manco Capas" and "Manià Dello" (p. 119), which appear to be intended for the usual forms, "Manco Capac" and "Mama Oello" (Mr. C. R. Markham would say that "Ccapac" and "Ocllo" are the really proper forms). At page 274, the account of the "couvade," the custom of the husband being put to bed or otherwise treated with reference to his wife's bearing a child, is compiled very inaccurately. Lastly, though references are generally given where long abstracts have been made from books of travel, Dr. Brown seems somewhat apt to make statements and use arguments without due mention of the sources whence he derived them. One consequence is, that he makes himself personally responsible for any blunder in the matter he thus appropriates. Thus, at page 147 a passage is inserted of which the following is part:—"In the Ladrone Islands, the Spaniards found the natives unacquainted with fire; and when Magellan set fire to the huts of the Marian islanders, they looked upon the flame as a living creature which fed upon wood." Unless my memory deceives me, this passage is copied out of Büchner's "Man in the Past, Present, and Future," and has been already commented on in NATURE, not only as embodying statements which have been disproved,

but as showing a certain geographical weakness in the writer, who did not know that the Ladrone and the Marian Islands are the same. E. B. T.

OUR BOOK SHELF

Typhoid Fever: its Nature, Mode of Spreading, and Prevention. By William Budd, M.D., F.R.S. Pp. 193. Three plain and one coloured lithograph. (Longmans, 1873.)

THIS handsome volume is a thesis on the question of how typhoid or enteric fever is propagated. Dr. Budd adopts what is known as the contagion theory, and believes that every case of the disease is the result of direct poison, conveyed either by the air or more frequently in water, from the intestine of one patient to that of another. This theory is generally disbelieved by the best medical authorities in London and Paris; but, as Dr. Budd points out, it is not in large towns that the transmission of disease can best be traced. He describes with minute exactness as to time, place, and other important conditions, outbreaks of this terrible disease in secluded country villages, in schools, and other isolated institutions, where he was able to trace the steps of the epidemic from house to house or from room to room. We believe that a candid perusal of these cases will bring the conviction that the theory of contagion is fairly proved. Many of them are at all events almost decisive against the theory that this enteric fever is "pythogenic," *i.e.* is the result of a poison which may be produced by any decomposing sewage under favourable circumstances, without previous contamination from a diseased person. The practical importance of the question is, that if enteric fever only spreads as Dr. Budd and other contagionists maintain, it is possible, and therefore of the utmost importance, to check its propagation. A great part of the book is devoted to this point, and the mode of destroying diseased products is carefully detailed.

One obvious objection to the contagion theory is that it only accounts for the spread, and not for the origin, of the fever. But, as Dr. Budd argues, the same applies to small-pox and every other undoubtedly contagious disease. However the first case came about, no one supposes that fresh ones now arise spontaneously, any more than naturalists who believe that worms and buttercups once came into being for the first time, expect to find a worm appear in a drop of water without an egg, or a buttercup in a meadow without a seed.

The comparison of typhoid disease to the eruption of small-pox, which is revived by Dr. Budd, has been long and deservedly abandoned: indeed the strictly pathological part of this book is the least satisfactory. Notwithstanding a somewhat "drawing-room" appearance, it is no doubt intended for pathologists and physicians to study; and for them we cannot see the advantage of the four illustrations, one of which forms an elaborately coloured frontispiece; they show nothing but what has often been figured before, and is now universally familiar. The style also is now and then too ambitious, suggesting rivalry with the wretched newspaper writing quoted on p. 110 as "lively and facile." On the whole, however, the book is as solid as it is earnest, and may be compared without detriment with Dr. Macnamara's well-known work defending an almost identical theory and practice with regard to the propagation and prevention of Asiatic cholera.

The facts and arguments contained in it will no doubt be duly weighed by the medical profession, and the public will benefit by the result. P. S.

Inorganic Chemistry, Elementary. By Raphael Meldola, F.C.S. (London: Thomas Murby, 1873.)

THE present little volume constitutes one of a series produced by the same publishers as "Science and Art Department Text-books." We must congratulate Mr. Meldola on having produced in a small compass a thoroughly good and sound introduction to the science of chemistry, and it is all the more welcome in these days of "Science Series," when so many badly done "Text-books" are being produced. The information is well and clearly stated, and is sufficiently free from technicalities to be easily understood by the beginner. The book is plainly and well printed, but we cannot congratulate the publishers on the execution of the few and simple woodcuts, every one of which has been spoiled in the cutting. We hope that in a future edition the work will receive better treatment, as a well-done woodcut is a great aid to the beginner in understanding his author's descriptions of various experiments.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

The Photographic Society

THE sweeping condemnation of the Photographic Society conveyed in an article in NATURE, vol. ix. p. 263, can only have been written under a want of knowledge or misrepresentation of facts. I will not say one word about any dissension which may exist in the Society, but as the statements you have published are calculated to injure the Society very materially, I will ask you, in common justice, to make public the transactions of the Society for the past year, so that the readers of NATURE may judge for themselves whether in a body which does not profess to be a purely scientific one, science is altogether ignored, whether "no man of eminent scientific capacity takes part," and whether the society is altogether beneath contempt as at present conducted. This I ask you to do not only in justice to the society, but to the gentlemen whose names are mentioned below.

1873. January meeting. "The Photographic Operations at the Royal Observatory in connection with Magnetical and other records," by James Glaisher, F.R.S.; "Instantaneous Microphotography," by E. J. Gayer, M.D.

February.—"On the Principles of the Chemical Correction of Object-Glasses," by Prof. G. G. Stokes, D.C.L., Sec. R.S.

March.—"A Contribution to the Early History of Photography," by H. Baden Pritchard, F.C.S.

April.—"Uranium Printing," by John Spiller, F.C.S.; "The Chemical Theory of the Latent Image," by Capt. Abney, R.E., F.C.S., F.R.A.S.

May.—"Improvements in Carbon Printing," by Mons. A. Marion.

June.—"Remarks on three Wet Processes," by Jabez Hughes; "Photo-collotype Printing," by Capt. Waterhouse, B.S.C.

December.—"Photography in the Arctic Regions," by Lieut. Chermside, R.E.

So far as investigations are concerned, I can mention two, at least, now being undertaken by members of the society, touching the process and nature of film best suited for the Transit of Venus observations.

BADEN PRITCHARD, Hon. Sec.

9, Conduit Street, W., Feb. 7

Animal Locomotion

THERE are two or three points in Dr. Pettigrew's new book as to which, perhaps, many of your readers in common with myself would be glad of a little light. First, in speaking of the gannet, he says: "Each wing, when carefully measured and squared, gave an area of 19½ square inches." But how is such an area obtained from the dimensions given? They are: "girth of trunk, 18 inches," *i.e.*, about 5 inches for its width; "expanse of wing from tip to tip across the body, 5 feet," so that each wing would stretch about 33½ inches from root to tip; "across secondaries, 7 inches," and this we may take as about the average width of the wing. Multiplying length of wing by width (33½ × 7), we get therefore an area of 234½ square inches. Similarly Dr. Pettigrew assigns the heron's wing an area of 26 square inches, although the dimensions he gives yield an area of about 311 square inches. A friend of mine has the temerity to suggest that for some reason or unreason Dr. Pettigrew has

divided the true area by 12, for so 234½ (if we neglect the half inch) gives just 19½, and 312 instead of 311 gives 26.

But (as a second matter) my friend's notion of Dr. Pettigrew's arithmetic receives some colour from the sentence following the one before quoted, viz., "The wings of the gannet, therefore [each wing being supposed 19½ square inches], furnish a supporting area of 3 feet 3 inches square." So of the heron. Having told us that the area of each wing is 26 square inches, he says, "Both wings consequently furnish an area of 4 feet 4 inches square." Here, surely, square inches have been treated as if they were linear, and only 12 of them instead of 144 reckoned to the square foot!

Once more (as was observed in your review a week or so ago), Dr. Pettigrew maintains, in opposition to all other experimenters, that in flight the downward stroke of the wing is directed forwards and not backwards. Now, to say nothing of the "singularity" of representing the wings in his own case as concavo-convex, and in that of his opponents as flat (much to the detriment of the latter), the whole of Dr. Pettigrew's "mathematical demonstration" of his position is so extremely original that I fear for the uninitiated it is only explaining *obscurum per obscurius*. Would he condescend to accepted methods and prove his case by the parellelogram of forces? As it is, his proof amounts simply to this:—"As the under surface of the wing, which is a true kite, looks upwards and forwards, it tends to carry the bird upwards and forwards." No doubt, if the wing remain still, and the bird have already a sufficient velocity. A kite is sustained or elevated by an extraneous force, either the wind impinging against its under surface, or *vice versâ* when the boy runs. But whence comes the bird's motion, before its wings can act as kites? Dr. Pettigrew nowhere tells us this, but starts with his bird already flying. Thus he says:—"The bird, when flying, is a body in motion. It has already acquired momentum. If a grouse is shot on the wing, it does not fall vertically downwards, as Borelli and his successors assume [Shade of Borelli!], but downwards and forwards. The flat surfaces of the wings are consequently made to strike downwards and forwards, as they in this manner act as kites to the falling body, which they bear or tend to bear upwards and forwards." Here it is unmistakeable that the function of the wings in generating velocity is confounded with their function in directing the velocity already generated; just as if one should confound a steamer's rudder with her screw. The question is, How do the wings generate velocity? In this respect it is immaterial whether the bird is at rest or in motion. But to this there can be but one answer, at least if we are still to believe that "action and reaction are equal and opposite;" the answer that is, that everybody gives but Dr. Pettigrew. The downward motion of the wing is wholly concerned with sustaining or elevating against gravity. A backward movement must carry the bird forward; Dr. Pettigrew's forward movement must make it fly tail first.

JAMES WARD

Trinity College, Cambridge, Feb. 2

YOUR reviewer resorts to very strong language, without, it appears to me, justifying his procedure. In reviewing my volume he exclaims, "Imagine our disappointment on finding that, instead of the work being by the hand of a master, its author is deficient in the knowledge of the first principles of physics, and of the undoubted meaning of some of the most simple terms employed in the science; his argument, if it may be so called, being but little more than a long series of vague and fanciful analogies, incorrectly stated physical facts, and untenable theories." . . . "We must say that we expected better things of Dr. Pettigrew, and regret that he has not, before now, learned that there are errors in his methods and results that cannot be tolerated by a thinking public, which prefers accurate reasoning rather than dogmatic statement, and well-grounded fact to fanciful analogy" (NATURE, vol. ix. p. 221). One would naturally have expected after such announcements an exposure of false theories and a criticism of the nomenclature employed, but Mr. Garrod condescends upon neither. He takes refuge in general statements and implies what he does not attempt to prove.

He states, *e.g.* "that it is at present impossible to obtain from any form of fuel, a sufficient percentage of the potentiality which it possesses for doing work, to work an engine sufficiently compact and light for the wings which it has to drive." Now this is utter nonsense. In 1868 Mr. Stringfellow, of Chard, Somersetshire, exhibited at the Crystal Palace a flying machine which with its engine, boiler, water, fuel, flying surfaces, and propellers only weighed 12 lbs. The engine of this machine exerted the third of a horse power and obtained the 100*l*. prize of the Aëronautical Society of Great Britain as being at once the lightest and most powerful steam-engine ever made.

What bird weighing 12 lbs. can Mr. Garrod inform me exerts a third of a horse power in flying?

This one fact proves that in the ordinary steam-engine we have a power more than equal to the production of flight.

Mr. Garrod takes exception to my statement that "weight when acting upon wings, or, what is the same thing, twisted inclined planes, must be regarded as an independent moving power."

This point will be best illustrated by an example. If a gannet drops from a cliff with *expanded motionless wings* it can sail for an incredible distance, the weight of the body dragging upon the wings, doing the principal part of the work. This is a matter of observation, and the principle may be exemplified by the following simple experiment. If an apparatus composed of two quill feathers stuck in the end of a cork be made to fall from a height it will be found to travel *downwards and forwards* in a curve, the forward curve equalling half the space through which the apparatus descends. Here we have no muscular movement to direct or influence the motion in any way, and it certainly seems to me to afford an explanation of the manner in which mere *weight*, or gravity acting upon weights, may by the aid of wings be made to propel a body from one point to another.

Mr. Garrod proceeds—"After such indications of imperfect knowledge, nothing in the way of mechanical theories could cause surprise, and we are therefore not astonished to find it laid down as the fundamental principle of flight, that *the up-stroke of the wing aids in propulsion*, and that in the down-stroke *the inferior surface of the wing is directed downwards and forwards*." If Mr. Garrod attempts to elevate a natural wing or an artificial one properly constructed, even in a strictly vertical direction, he will find that it inevitably darts upwards and forwards in a curve and carries the hand with it. In this manner, as experiment proves, *the ascent of the wing aids in propulsion*. If again Mr. Garrod attempts to depress the wing vertically downwards, he will as certainly find that it darts *downwards* and *forwards* in a curve, the hand being carried in the direction specified. The upward forward and downward forward curves, being united as they are in flight, give a *waved track*. If the wings did not dart *forwards* both during their ascent and descent the body of the bird could not be transferred from one place to another in a horizontal waved line which it is. Mr. Garrod is evidently imperfectly informed on the subject of flight, for he inquires "Who can see any close relation between the flight of birds and that of a kite?" The merest tyro in mechanics will, I think, perceive this on a moment's reflection. The kite is pulled *forwards* on the moving air by the string. The kite formed by the wings of a bird is *pushed* forwards on the moving air by the weight of the body.

I do not forget, as Mr. Garrod insinuates, that a kite requires a string. The following passage, written in 1867, will show this. "The wing of a bird acts after the manner of a boy's kite, the only difference being that the kite is pulled forwards upon the wind *by the string* and the hand, whereas in the bird the wing is pushed forwards on the wind by the weight of the body and the life residing in the pinion itself." *

Mr. Garrod's words are—"Dr. Pettigrew seems to forget that a kite needs a string, and yet, backed by his false analogy, *he has the presumption* to quote the experimental verifications and opinions of such able and ingenious thinkers as Borelli and Marey, the authors of the true theory of flight, only to reject them." To one who has experimented on the subject of flight for the last 10 years, the term *presumption* in this sentence sounds strange. One may, I venture to think, without presumption, differ from another after such mature deliberation. Marey's theory of flight, which is nearly, if not identical, with my own, was not promulgated till nearly two years after I had published mine. This point will be fully discussed in the *Athenæum* of Feb. 14. In fact Marey frankly admitted this in a letter to the French Academy of Sciences in reply to a reclamation lodged by me with that learned body.

His words are:—"J'ai constaté qu'effectivement M. Pettigrew a vu avant moi, et représenté dans son Mémoire, la forme en 8 du parcours, de l'aile de l'insecte; que la méthode optique à

* On the various modes of flight in relation to aëronautics: Proc. Roy. Instit. of Great Britain, March 22, 1867.

laquelle j'avais recours est à peu près identique à la sienne. . . . Je m' empresse de satisfaire à cette demande légitime, et je laisse entièrement la priorité sur moi, à M. Pettigrew relativement à la question ainsi restreinte." (*Comptes Rendus* for May 16, 1870, p. 1093.)

The next point which Mr. Garrod takes up is the "induced currents" of the wing. I state that "the efficiency of the wing is greatly increased by the fact that when it ascends it draws a current of air up after it, which current, being met by the wing during its descent, greatly augments the power of the down-stroke. In like manner, when the wing descends, it draws a current of air down after it, which, being met by the wing during its ascent, greatly augments the power of the up-stroke." This is simply a statement of fact, and if Mr. Garrod causes a natural or artificial wing to vibrate he will find that the wing takes a greater catch of the air when a down- and up-stroke or an up- and down-stroke are made in rapid succession, than when a single stroke is made either in the one direction or in the other. This point becomes especially clear if a large artificial wing be constructed on the insect type and made to vibrate in a horizontal direction. If such a wing have its anterior margin slightly elevated and made to travel from right to left of the operator it draws after it a current of air which, being met by the wing when it is reversed and made to pass from left to right, acts as an autumn breeze to a kite. The wing literally flies on the current which it creates. It ascends at each thrust and carries the hand of the operator with it. Similar remarks are to be made of the tail of the fish. It is in this way that the *back air* and *back water* are utilised, and herein lies the excellence of the elastic reciprocating screw, as found in Nature, and as contra-distinguished from the rigid rotatory screw employed in navigation.

Mr. Garrod, adducing no proof in refutation of this and similar experiments, states "that these *induced currents* are of no real service in flight, because in their production there is as much force lost as there may be gained from their subsequent employment on the reversal of the action of the wing, if the bird's body has not advanced sufficiently far to be in each stroke beyond the range of their action, which is probably the case." On what authority does Mr. Garrod make this assertion? When a bird flies in still air, the wing of necessity must vibrate. The quicker it vibrates the more marked the reaction obtained from the air, and the greater the elevating and propelling power. The *induced currents* powerfully contribute to this reaction from the fact that the wing and the air are both moving, and moving in opposite directions. This, as explained, is a matter of experiment, and can readily be verified.

Lastly Mr. Garrod attacks my views on muscular movements. Here again he adduces no counter-proof, and, adhering to the old doctrine, contents himself by saying, "We are not ashamed to say that such has always been and still is our idea." This is not saying much. He takes exception to my statement that muscles have a centripetal or shortening power and a centrifugal or elongating power. Can he inform me how the left ventricle of the heart opens after a vigorous contraction, in which all the blood contained in the ventricular cavity is ejected and the ventricle converted into a solid muscular mass, if not by a spontaneous *elongation* of all its fibres?

Edinburgh, Jan. 27 J. BELL PETTIGREW

Specific Gravity of Sea-water

IN reference to Mr. Strachan's letter in NATURE, vol. ix. p. 183, calling attention to the discrepancy between Dr. Frankland's results and my own, permit me to state that they were not obtained from the same series of samples, and that the figures given by Dr. Frankland were, I believe, obtained by the use of a balance on shore, and also that from the way in which his specimens were packed, they were not liable to any appreciable loss by evaporation. They were not, however, taken from that part of the North Atlantic which was examined during the time that I was on board the *Porcupine* in 1869, to which alone my observations refer. My own results were obtained, as stated on p. 503 of "The Depths of the Sea," by delicate glass hydrometers, so graduated that the sp. gr. could easily be read to the fourth decimal place. Two instruments only were employed for the 105 observations made, and though they gave identical results, I had no opportunity of comparing their indications with the results obtained by a balance from the same specimen of water. I may remark here, however, that though the *absolute* results may not be quite correct, the relations between the sp. gr. of surface, intermediate, and bottom waters, pointed out on p. 505 of "The Depths of the Sea," as well as the range of variation, are probably very near the truth, since the same instruments were employed in all the determinations, and at the end of the series they indicated the same as at the commencement, when placed in a test solution, which was preserved for the purpose of detecting possible variations in the instruments themselves.

Clifton, Bristol, Jan. 17 WM. LANT CARPENTER

THE LINNEAN SOCIETY

WE regret to hear of an unpleasant event which took place at the meeting of the Linnean Society on Thursday last (5th inst.). So far as we have been able to gather the particulars they are as follows.

When the usual minutes had been read at the commencement of the meeting, a Fellow of the Society rose in his place and endeavoured to propose a motion reflecting upon the conduct of the President at the preceding meeting. The President (Mr. George Bentham, F.R.S.) ruled that the Fellow was out of order and that his motion could not be put, and requested the would-be mover of it to sit down in his place. In spite of frequent calls to order, however, this gentleman persisted in his endeavours to bring forward his grievances, and to address the meeting. At last Mr. Bentham, finding that his efforts to preserve order were vain, and that the mover of the motion (who had given no sort of notice of his intentions) was backed up by a body of clamorous friends assembled specially for the purpose, quitted the chair and left the meeting-room, followed by the Secretary and all the other members of the Council present.

As the chair of the Linnean Society can only be taken by a member of Council, the meeting thus came to a premature end, much to the disappointment of those who had assembled to hear Mr. W. K. Parker read his paper on the osteology of the woodpeckers.

We regret to have to add that, in consequence of this untoward event, Mr. Bentham has tendered his resignation as President of the Society. But we trust that the Fellows who caused the disturbance will, upon reflection, feel that however much they might have considered themselves aggrieved by the President's decision at the previous meeting, they were not justified in the course they pursued. In all meetings the decision of a chairman upon a point of order is held to be final, at all events for the occasion. More especially should this be the case in a learned society assembled for the discussion of scientific problems, and not for vulgar wranglings and disputes upon immaterial subjects.

We trust therefore that an ample apology will be offered to the President by these gentlemen, and that he will be induced to retain his chair until the approaching anniversary meeting of the Society, when he had already given notice of his intention not to accept re-nomination. The great services which Mr. Bentham has rendered to Science generally and to the Linnean Society in particular, are too well known to the readers of NATURE to render it necessary for us to descant upon them in these columns. The Linnean Society has just acquired a new and most convenient abode in the apartments at Burlington House, recently provided for it by the liberality of the country, and it would be a great misfortune if disunion should succeed in marring the work of those who are now endeavouring to make the Society still more useful and more prosperous than it has been in past times.

POLARISATION OF LIGHT*

IV.

THE phenomena exhibited by selenite are also produced by other crystals, but the facility with which plates of the former substance can be obtained, causes them to be generally used in preference to others. There is, however, a peculiar class of crystals, of which quartz, or rock crystal, is the most notable, which gives rise to effects different from those hitherto described.

* Continued from p. 205.

If a ray of light pass through a plate of quartz which has been cut perpendicularly to the axis, or line parallel to the main planes bounding the crystal, it is as usual divided into two; but the vibrations in each ray, instead of being rectilinear and at right angles to one another, are circular and in opposite directions. That is to say, if the motion of vibration in one ray is directed like the hands of a clock, that in the other is directed in the opposite sense; and the light in each ray is then said to be circularly polarised. The motion of a series of particles of ether, which when at rest lie in a straight line, is circular, and, as in plane polarisation, successive; and consequently, at any instant during the motion such a series of particles will be arranged in a helix or corkscrew curve. The sweep of the helix will follow the same direction as that of the circular motion; and, on that account, a circularly polarised ray is spoken of as right-handed or left-handed, according to the direction of motion. A right-handed ray is one in which, to a person looking in the direction in which the light is moving, the plane of vibration appears turned in the same sense as the hands of a watch. Or, what is the same thing, to a person meeting the ray, it appears turned in the opposite sense, viz., that in which angles when measured geometrically are usually reckoned as positive.

The question, however, which mainly concerns us is the condition of the vibrations after emerging from the plate of quartz and before entering the analyser. In the passage of the ray through the plate the ether is subjected to a double circular motion, one right-handed, the other left-handed; but, as one of these motions is transmitted with greater velocity than the other, it follows that at any given point and at the same instant of time one of the revolutions will, in general, be more nearly completed than the other, or, to use an expression adopted in plane polarisation, there will be a difference of phase. The motions may be represented by two clock hands moving at the same rate in opposite directions, and the difference of phase by the angle between them when one of them is in the position from which angles are reckoned. As both are supposed to move at the same rate, they will have met in a position midway between their actual positions; and if we consider a particle of the ether (say) at the extremity of the clock-hands, it will be solicited when the hands are coincident by forces producing two opposite circular motions. Now, whatever may have been the forces or structural character within the crystal whereby this double circular motion is perpetuated, it is clear that when the ray emerges into air the particle of ether immediately contiguous to the surface of the crystal will be acted on by two sets of forces, one whereby it would be caused to follow the right-handed and the other the left-handed rotation. Each of these may, as is well known, be represented by a pair of forces, one directed towards the centre of the circle, the other in the direction of the motion and at right angles to the first, or, to use geometrical language, one along the radius and towards the centre, the other along the tangent and in the direction of the motion. The two forces acting along the tangent being in opposite directions will neutralise one another, and the resultant of the whole will, therefore, be a force in the direction of the centre. The particle in question, and consequently all those which following in succession serve to compose the entire ray until it enters the analyser, will vibrate in the direction of the diameter drawn through the point under consideration; or, to express it otherwise, the ray will be plane-polarised, and the plane of vibration will be inclined to the plane from which angles are measured by an angle equal to half the difference of phase on emergence due to the thickness of the crystal. The retardation being the same absolute quantity for all rays, will, as in the case of plane polarisation, be a different fraction of the wave-length for rays of different colours, and will be greater for the shorter waves than for the longer. Hence the planes of vibration of the different coloured rays, after emerging from the quartz, will be differently inclined. Each ray will therefore enter the analyser in a condition of plane polarisation; and if the analyser be turned round, it will cross the vibrations of the various coloured rays in succession, and extinguish each of them in turn. Each of the images will consequently exhibit a gradual change of colour while the analyser is being turned; and the tints will be, as explained before, complementary to those which are successively extinguished. For a given plate of quartz the order of the tints will be reversed when the direction of rotation of the analyser is reversed. But it should be here explained that there are two kinds of quartz, one called right-handed and the other left; and that, for a given direction of rotation of the analyser, these cause the colours to follow one another in opposite orders. A similar effect is produced by turning the polariser round in the opposite direction.

The angle of rotation of the plane of vibration for any particular colour varies, as stated above, with the thickness of the plate; while for a given thickness it increases nearly as the square (product of the quantity into itself) of the wave-length decreases. In mathematical language it varies approximately inversely as the square of the wave-length. If this law were accurately true, the product of the angles of rotation into the square of the corresponding wave-lengths (λ) would be the same for all rays. The following are some measurements made by Brock, with a quartz plate one millimetre thick, which show that the law may be considered as true for a first approximation.

Rays	Rotations	Rotations $\times \lambda^2$.
B	15° 18	7,238
C	17° 15′	7,429
D	21° 40′	7,511
E	27° 28′	7.596
F	32° 30′	7,622
G	42° 12′	7,842

If the colours exhibited by a plate of quartz when submitted to polarised light be examined by a spectroscope, in the way described when we were speaking of selenite, the spectrum will be found to be traversed by one or more dark bands, whose position and number depend upon the thickness of the plate. But there will be this difference between plane and circular polarised light, that if the analyser be turned round, the bands will never disappear, but will be seen to move along the spectrum in one direction or the other, according as the plate of quartz be right-handed or left-handed, and according to the direction in which the analyser is turned. This is, in fact, identical with the statement made before, that the analyser in its different positions successively crosses the plane of vibration of each ray in turn, and extinguishes it.

This being so, it is clear that a change of colour exhibited by a quartz plate when submitted to plane-polarised light and examined with an analyser, forms a test of a change in the plane of original polarisation. And if the plate be composed of two parts, one of right-handed, the other of left-handed quartz, placed side by side, any change in the plane of polarisation will affect the two parts in opposite ways. In one part the colours will change from red to violet, in the other from violet to red. At two positions of the polariser, or analyser, the colours must be identical. With plates, as usually cut, one of these identities will be in the yellow, the other at the abrupt passage from violet to red, or *vice versâ*. In this case the field appears of a neutral tint, *teinte sensible* or *teinte de passage*, as the French call it, and the slightest change in the plane of polarisation exhibits a marked distinction of colour, one part verging rapidly to red, the other to violet. This arrangement is called a biquartz, and affords a very delicate test for determining the position, or change of position, of the plane of polarisation, especially in cases where feebleness of light or other

circumstance interfere with the employment of prismatic analysis.

If the thickness of the plate be such that the difference of rotation of the planes of vibration of the rays corresponding to the two ends of the visible spectrum (or, as it is sometimes termed, the "arc of dispersion") be less than 180°, there will be one dark band in the spectrum; because there can then be only one plane of vibration at a time at right angles to that of the analyser. If the arc of dispersion is greater than 180° and less than 360°, there will be two bands. And so on for every 180° of dispersion.

This mode of examination by means of prismatic analysis is the most accurate yet devised for measuring the angle of rotation produced by circular polarisation; especially if solar light be employed, and the fixed lines used to form a scale of measurement.

The property of circular polarisation is, however, not confined to quartz. Among solids, chloride of sodium is the only other known instance, but among fluids and fluid solutions there are not a few.

The following list is given by Verdet. The angles have reference to the red rays given by a plate of glass coloured with oxide of copper, and are affected with the sign + in the case of right-handed, and with – in the case of left-handed rotation. The length of the column of the solution is in every case one decimetre.

Essence of turpentine . . .	−29°·6
,, lemon . . .	+55°·3
,, bergamot . . .	+19°·08
,, bigarade . . .	+78°·94
,, aniseed . . .	− 0°·70
,, fennel . . .	+13°·16
,, carroway . . .	+65°·79
,, lavender . . .	+ 2°·02
,, peppermint . . .	+16°·14
,, rosemary . . .	+ 2°·29
,, marjorum . . .	+11°·84
,, sassafras . . .	+ 3°·29
Solution of sugar 50 per cent. .	+33°·64
,, quinine 6 per cent. in alcohol .	−30°.

It will be noticed that the rotary power of all these substances is much less than that of quartz.

A mixture of liquids, one or both of which is active, generally exhibits a rotatory action represented by the sum or difference of their separate powers (a neutral liquid being considered to have a power represented by 0); but this law is true only when no chemical action takes place between the elements of the mixture. Saccharine solutions vary not only in the amount but also in the character of their power of rotation; thus cane sugar is right-handed, but grape sugar left-handed.

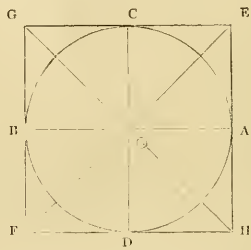
The property in question has been turned to practical use by employing the rotatory power of a saccharine solution as a measure of the strength of the solution. For this purpose a tube containing the solution to be examined is placed between two Nicol's prisms. The simple fact of circular polarisation is proved by a feeble exhibition of the phenomena shown by a plate of quartz cut perpendicularly to the axis. But for accurate measurement various expedients have been adopted. If a biquartz be inserted behind the analyser (the end of the apparatus next the eye being considered the front), then for a certain position of the analyser the two halves will appear of the same colour. When the tube for examination is inserted the similarity of colour will be disturbed; and the angle through which, right or left, the analyser must be turned in order to restore it will be a measure of the rotary power of the fluid.

Another method is as follows:—Use a single quartz instead of a biquartz; in front of it place a pair of quartz wedges, with the thin end of one opposite the thick end of the other; the outer surfaces having been cut perpendicularly to the axis. If the plate be right-handed, the wedges must be left-handed, and *vice versâ*. The wedges must be made to slide one over another so as together to form a plate of any required thickness, and a scale connected with the sliding gear registers the thickness of the plate produced. When the tube is removed the wedges are adjusted so as to compensate the quartz plate, and their position is considered as the zero point of the scale. When the tube is replaced, the wedges are again adjusted so as to compensate the action of the fluid in the tube, and the difference of the readings gives the thickness of quartz necessary for the compensation. The rotatory effect of a given thickness of quartz being supposed known we know at once the effect of a thickness of the fluid under examination equal to the length of the tube.

Another method has been based upon the principle of Savarts bands; but sufficient has perhaps here been said to illustrate the principle of the saccharometer.

Circular polarisation may, however, be also produced by other means, namely, by total reflexion, and by transmission through doubly-refracting plates of suitable thickness.

It will perhaps be best to begin with the last. And in order the better to understand the process we must consider briefly the result of compounding two rectilinear vibrations under different circumstances.



Suppose a particle of ether to be disturbed from its point of rest O in a direction O A. The attraction of the particles in its neighbourhood would tend to draw it back to O; and let O A be the extreme distance to which under these attractions it would move. Having reached A it would return to O, and passing through O with a velocity equal to that with which it started under the disturbing force, it would move to a point B equidistant from O with A, but in the opposite direction. And if, as is generally supposed, the ether is perfectly elastic, or that there are no internal frictions or other conditions whereby the energy of motion is converted into other forms of energy, the oscillations or vibrations of the particle between the points A and B will continue indefinitely. Now suppose that while these vibrations are going on, a second disturbing impulse, equal in intensity, but in a direction at right angles to the first, be communicated to the particle, it is clear that the effect on the motion of the particle will be different according as it takes place at the point of greatest velocity O, or at that of no velocity A or B, or at some intermediate point. Our object is to consider the effects under these various circumstances.

A complete vibration consists in the motion from O to A, thence to B, and finally back to O; so that if O be the starting point the passage through A will be removed one-fourth, the passage through O from A towards B will be one-half, the passage through B will be three-fourths, and the passage through O from B to A a complete vibration from the commencement. This being so, suppose that the second impulse be communicated while the particle is at O on its way towards A, then the impulses may be considered as simultaneous and the vibrations to which they give rise will commence together, and the waves of

which they form part will be coincident. If the second impulse take place when the particle is at A, the two sets of vibrations or waves to which they belong will have a difference of phase (*i.e.* the first will be in advance of the second) equal to one-fourth of a vibration or one-fourth of a wave-length. If the second impulse take place when the particle is at O on its way to B, the difference of phase will be half; if when it is at B the difference will be three-fourths of a wave-length.

The particle being at O, and subject to two simultaneous impulses of equal strength, one in the direction of A, the other in that of C, must move as much in the direction of C as in that of A, that is, it must move in a straight line equally inclined to both, namely O E in the same figure. And inasmuch as the two impulses in no way impede one another, the particle will move in each direction as far as it would have done if the other had not taken place. In other words, if we draw a square about O with its sides at distance equal to O A or O B, the extent of the vibration will be represented by O E where E is a corner of the square. The complete vibration will then be represented by the diagonal E F in the same way as it was by the line A B in the first instance. If the impulse had been communicated at the instant of passage through O on the way to B, it is clear that a similar train of reasoning would have shown that the vibration would have been in the other diagonal G H. We conclude, therefore, that if two sets of rectilinear vibrations, or plane waves, at right angles to one another combine, then when they are coincident they will produce a rectilinear vibration, or wave, whose plane is equally inclined to the two, and lying in the direction towards which the motions are simultaneously directed. In the figure this is represented by the dexter diagonal When the two sets of waves have a difference of phase equal to half a wave length, their combination gives rise to a wave represented in the figure by the sinister diagonal.

Suppose now that the second impulse is communicated at the instant when the particle is at A; in other words, that the two sets of waves have a difference of phase equal to one-fourth of a wave-length. At that instant the particle will have no velocity in the direction of A B (for convenience, say eas wards), and will consequently begin to move in the direction of the second impulse, say northwards. But as time goes on the particle will have an increasing velocity westwards and a diminishing velocity northwards, it will therefore move in a curve which gradually and uniformly bends, until when it has reached its greatest distance northwards it will be moving wholly westwards. And as the motion not only will be the same in each quadrant, but would be the same even if the directions of the impulses were reversed, it is clear that the curvature of the path will be the same throughout, that is to say, if two sets of waves of the same magnitude in planes perpendicular to one another, and with a difference of phase equal to one-fourth of a wave-length combine, they will produce a wave with circular vibrations.

If the second impulse be given when the particle arrives at B, that is, if the waves have a difference of phase equal to three-fourths of a wave-length, similar considerations will show that the motion will be circular, but in the opposite direction.

Suppose, therefore, that we allow plane-polarised light to fall upon a plate of doubly refracting crystal cut perpendicularly to the axis in the case of a uniaxal crystal, or in the case of a biaxal to the plane containing the two axes, say a plate of mica which splits easily in that direction; then the vibrations will, as before explained, be resolved in two directions, at right angles to one another. And further, if the original directions of vibration be equally inclined to the new directions, *i.e.*, if it be inclined at 45° to them, the amount or extent of vibration resolved in each direction will be equal. Further, if the thickness of the plate be such as to produce retardation or difference of phase equal to a quarter of a wave, or an odd number of quarter wave-lengths, for the particular ray under consideration; then the two sets of vibrations on emerging from the mica plate will recombine, and, in accordance with the reasoning given above, they will form a circular vibration, left-handed or right-handed according as the retardation amounts to an integral number of three-quarter wave-lengths or not.

It thus appears that a plate of mica which retards one of the sets of waves into which it divides an incident set by an odd multiple of quarter-wave lengths, affords a means of producing circular from plane polarisation. It remains to be shown that, with the same plate in different positions, right or left handed circular polarisation may be produced at pleasure. Suppose that the original vibrations are in the direction E F in the foregoing figure; the mica plate will resolve them into the two directions A B, C D, one of the rays, say the first, will be transmitted with greater velocity than the other, and the vibrations along C D will be one-fourth of a wave-length behind those along A B. This will correspond to the case discussed above, and will give rise to a circular vibration in a direction opposite to that of the hands of a clock. Suppose, however, that the plate be turned round through a right angle, so that the vibrations which are transmitted with greater velocity are placed parallel to C D, and those which are transmitted with lesser along A B. The ray whose vibrations are along A B will then be a quarter wave-length in advance, or, what comes to the same thing, they are three-quarters of a wave-length in rear of the others; and this condition of things produces, as explained before, a circular vibration in a direction the reverse of the former. It thus appears that the plate placed in one direction will convert plane into right-handed circular polarisation; and if turned round through a right angle from that position will convert plane into left-handed circular polarisation. A like change from right-handed to left-handed circular polarisation, or *vice-versâ*, may obviously be effected by turning the orginal plane of polarisation through a right angle; so that it shall lie between lines of concurrent instead of between lines of discordant motion.

W. SPOTTISWOODE

(*To be continued.*)

A COMPLETE SPECIMEN OF A PALÆOTHERIUM

FROM *La Nature* we learn that the palæontological collection of the Museum of Natural History of Paris has just been enriched by the addition of a new specimen of very great scientific interest, which is the entire skeleton of *Palæotherium magnum*, imbedded in a large block of gypsum and marl, the whole being exhibited in the anatomical department of the museum.

The *Palæotherium magnum*, whose name alone indicates its ancient existence, was first recorded by the great French naturalist Cuvier, in his celebrated "Recherches sur les Ossemens Fossiles." It is an animal which is entirely extinct, without any present representative. Individuals of the species must have been extremely abundant during the period that it existed. Modern zoologists place it among the Perissodactylates, that is to say, with the at present existing rhinoceros, tapir, and horse. It forms part of the fauna which is found abundantly embedded in the deposits of gypsum. All palæontological collections, even the most humble, have for a long time been provided with the remains, or more or less complete portions of this fossil form, but none have yet had the good fortune to obtain a complete skeleton.

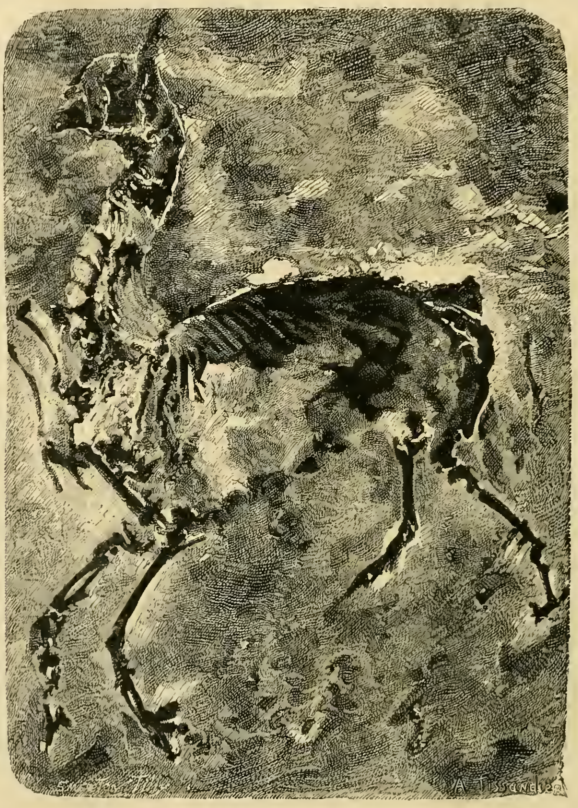
The principal result of the examination of the new specimen which we are describing has been to show that until now very inexact notions have been entertained as

to what this animal truly was when the proportions and general contour of the tapir were assigned to it, as was done even by Cuvier himself.

Far from being bulky and almost massive, as was thought, *Palæotherium magnum* is now evidently seen to be a very slender animal, with an extremely graceful carriage, with the neck longer than in the horse, and a general contour much on the same type as that of the Llama.

Without attempting a detailed study of its osteological structure, we may mention that *Palæotherium magnum* had a height a little less than that of a middle-sized horse Three toes are found on each of the feet; the head, much like that of a tapir, had most probably also the rudiment of a trunk; the femur has a third trochanter; the dentary system is composed, in each jaw, of six incisors, two canines, and fourteen molars, these latter corresponding with the same teeth in the rhinoceros.

Palæotherium magnum, like its congeners, of which about a dozen species are at present known, was herbivorous, and without doubt lived in large herds. Its existence carries us back to that age of our earth which is termed the Eocene period, and it is in the middle of that period, which comprises the gypsum deposits or their geological



PALÆOTHERIUM MAGNUM

equivalents, that its remains are discovered, as well as those of all the other species of the same genus.

Nevertheless it made its appearance even before the gypsum formation, its presence having been detected in the beds of coarse limestone, which are inferior to and therefore more ancient than that formation.

It is the plaster quarries of Montmartre, Pantin, and La Villette, near Paris, which have for a long time held the privilege of furnishing to palæontologists the numerous remains that are known of this fossil species. The Palæotherium, which forms the subject of this notice, was obtained from a plaster-quarry situated at Vitry-sur-Seine. It was, however, even a few days ago, as we see it to-day, exposed on one side, and on the other encrusted in its stony resting-place in the ceiling of a subterraneous gallery, a little more than four yards high. Only a few have visited it, although M. Fuchs, a civil engineer, the proprietor of the quarry where this magnificent specimen was found, offered to give it to the Museum.

The gift so generously offered was immediately accepted; and Prof. Gervais, with a scientific zeal which ought to be fully acknowledged, occupied himself with the direction of the important task of taking it intact to Paris.

MARS

THE characteristic appearance of this planetary body, long familiar to astronomers, has of late become generally known. Remarkable neither for situation, magnitude, brilliancy, retinue or complexity of arrangement, inferior in each of these respects to some, and in many of them to several of the members of the solar family, one circumstance alone invests it with a peculiar interest—its resemblance to ourselves. Such a resemblance obviously does not exist in the mightier and more nobly attended external planets: the banded skies of two and the strong atmospheric absorption of the two others revealed by the spectroscope, sufficiently show that they belong to classes

MARS IN 1862

mutually indeed dissimilar, but each differing, and perhaps widely, from our own. With the swift and fiery Mercury we can have as little sympathy; and though Venus would offer a more promising analogy, the configuration of her beautiful surface is not well seen or readily interpreted. Mars therefore remains; and while, fortunately for astronomers, he occupies such a position that his features are fairly accessible, they bear an aspect so comparatively intelligible that, whatever may be the case as to our other fellow-subjects in the solar monarchy, we are ready to claim that globe as a close relation of our own, inferior indeed in magnitude and importance, if importance is indicated by an attendant, but arranged in a corresponding manner by the Great Creator as the seat of life and intelligence.

Such a supposition has been gradually and surely advancing from an early period of telescopic astronomy. The polar whiteness detected by Huygens and Cassini I. as far back as 1672 would naturally suggest the idea of a snowy deposit, which assumed almost the form of certainty, when the elder Herschel showed that its extent was regulated by the Martial seasons, and that it wasted steadily down with the advance of vernal heat. From the obvious division of the surface into brighter and darker portions, the existence of an atmosphere at least would be inferred, so long as they were supposed to be variable; but as the evidence of their general permanence increased under the eye of Herschel I. about a century ago, this impression gave place to the more definite recognition of something corresponding to the outlines of lands and oceans, with occasional variation from atmospheric condensations; and thus by degrees we have been led to acknowledge, in that remote and otherwise unimportant globe, a most interesting counterpart of our own.

This conclusion has not, however, been attained by an uninterruptedly continuous or an uniformly satisfactory process of deduction; and even at the present time it is perhaps not universally received. Schröter referred the darker portions to atmospheric obscuration, a notion which pervaded others of his investigations, not to their advantage; and a more recent observer of considerable ability, the late Prof. Kaiser, of Leiden, whose decease in his 64th year took place July 28, 1872, has, in a very elaborate and interesting report of the work done on the planet at that observatory, expressed his doubts as to the certainty of the more customary inference. Whatever may be our own impressions on the subject, his criticisms and conclusions exhibit so much of the genuine spirit of an impartial student that some notice of them, as they are found in vol. iii. of the Annals of the Leiden Observatory, may be worth the attention of our readers. This observatory, it should be noted, is provided with a Merz achromatic of 7 (French?) inches aperture, and was therefore, under Kaiser's superintendence, fairly competent for physical researches commensurate with the present demands of science; as it is well known, and indeed especially brought out by the observations we are about to notice, that much larger telescopes are not invariably, or even generally, available in proportion to their magnitude. The addition, in 1872—too late therefore for a share in the professor's observations—of an $8\frac{1}{2}$ inch With-Browning reflector, will hereafter not only afford an interesting comparison of instruments, but if the result corresponds with others obtained elsewhere, will be found a step in advance as regards efficiency.*

In selecting Mars as the subject of special inquiry, Prof. Kaiser laid a solid foundation by consulting every work within his reach, representing or describing the physical aspect of the planet, from the earliest and rudest efforts in 1636 to the elaborate delineations of the present day. No less than 412 drawings thus passed through his hands: upwards of 320 others he could not procure; and the aggregate is doubtless much in defect of the existing total. He did however well in securing so many; more, probably, than any other areographer, if such a word may be allowed. But the result of their comparison and discussion was not as satisfactory as might be wished. The first specimens of representation were of course mere rude attempts. Those of Huygens, however, in 1659, discovered by Kaiser in his "day-book" (of which the most valuable portion was edited by him in 1847) are comparatively well drawn; and Hook, in 1666, caught the true character of what he saw, though Kaiser doubts whether his spots could be as readily identified as has been supposed. We next find Herschel I. taking up the subject

* A curious error on the part of Prof. Kaiser may here be noticed. He has referred (p. 23) to a drawing of Mars by Browning as having been taken with a silvered mirror by Barnes. This gentleman was merely the proprietor of the speculum, which, like the others mounted by that optician, was th work of a most accomplished artist, Mr. With, of Hereford.

in 1777, and continuing his observations till 1783. He first noticed the eccentric position of the two white spots in the polar regions, as well as their diminution from solar action; 5 out of his 31 figures show a broad white band passing obliquely across the disc, and he speaks of changes in the markings from passing clouds and vapours: some of his dark spots can be identified with more recent representations, but not the whole. Of the numerous drawings (217) of Schröter, Kaiser was unable to avail himself, as the Areographische Fragmente, rescued from the disastrous fire at Lillenthal in 1813, were left unpublished at his death. These, however, through the intervention of Dr. Peters of Altona, have subsequently been traced to their safe custody in the hands of Schröter's descendants, and have recently been thoroughly examined by Dr. Terby of Louvain, whose report has been published by the Belgian Académie Royale des Sciences. From the figures contained in this, and another interesting essay by the same astronomer, it appears that many coincidences may be traced between the views of Schröter and other observers, though his preconceived idea of the vaporous nature of the darker features deprived his observations of some of the value otherwise due to them as the results of eminent zeal and perseverance.

Passing by several observers of minor note, of whom Kaiser has given a minute enumeration, we reach the opposition of 1830, which the near concurrence of the aphelion of the Earth and the perihelion of Mars rendered eminently favourable, enlarging the apparent diameter of the latter to 23″·1. The close and systematic investigation then entered upon by Beer and Mädler forms a most important epoch in the progress of areography, and for the first time a series of drawings were executed, little resembling anything previously known, which have ever since been referred to with confidence as a starting point for future inquiries, and which, it might have been hoped, would have set many questions at rest: and so they did; but as Kaiser remarks, later representations have again unsettled points which had been supposed to have been then decided. The comparative failure of the same observers in subsequent oppositions admitted of explanation from the increased distance and altered presentations of the planet; and little advance was made by Mädler in 1841, even with the renowned refractor at Dorpat, to the care of which he had succeeded: the apparent diameter, then, however, was only 15″·1, its minimum, attained in 1837, being 13″·3. Of the near approach in 1845, when the disc was enlarged to 23″·5, no observations seem to have fallen into Kaiser's hands, excepting those of the American astronomer Mitchell. Confining ourselves still to the more important representations, at the expense of doing scanty justice to the Professor's elaborate memoirs, we find that 1854 produced the beautiful designs of Jacob, and 1856 the still more delicate ones of De La Rue, both great advances on anything previously published. In 1858, Secchi, who had been for some years at work at Rome, brought out a series of drawings in much harmony with themselves, but only partial agreement with previous delineations. At length came the favourable opposition of 1862, when the point was taken up by many of the first observers armed with some of the most powerful telescopes in existence; but the result, we regret to add, was very different from what might have been anticipated. Secchi, with his magnificent achromatic, Lassell and Rosse with their colossal reflectors, produced such an unsatisfactory and in part contradictory set of drawings as had never been published before. The weather was not always in fault; and though Mars was rather low, Lassell repeatedly found very sharp definition; Lord Rosse's excellent draughtsman once used a power of 1,200; and the quality of Secchi's instrument and sky compensated to a great extent for his smaller aperture; but then the expected clearing up of difficulties terminated in the annoyance of disappointment. Kaiser assures us that nowhere are there such discrepancies as between Rosse and Lassell, even when the same hemisphere was obviously in sight; it could hardly be imagined that they had the same spot in view: and Secchi is so far from setting the matter straight, that his figures scarcely seem to refer to the same body; and for any purpose of accurate deduction the Leiden Professor felt obliged to put all three aside. He is even induced to say, "the largest telescopes give the worst results, and show themselves very liable to mislead the observer: correct delineations of the celestial bodies require before all things a very practical designer that gives way to no fancies; and such a designer is not apt to possess the most powerful telescopes of the earth." We are here merely reproducing the censor's words, without venturing an opinion as to the soundness of his criticism.

But, fortunately as it would seem for areogrophy, instruments of more moderate dimensions were employed to better purpose during that and the subsequent opposition of 1864; and the agreement of the beautiful designs of Lockyer in the former year with those taken by Kaiser himself, then and in 1864, as well as with those of Schmidt and Phillips, was far more satisfactory: and the same might be said to a considerable extent as to Dawes, whose instrument, however, was of a superior rank.* The difference between Lockyer and Lassell, in one instance, was so wide, that identity of date alone proves that they had the same hemisphere under their eyes; while, on the contrary, the concurrence between Lockyer and Kaiser, though the latter speaks with great diffidence of his own designs, justified him in believing that a pretty correct representation had been attained of a broad girdle round the equator.

The labour which the Leiden professor has bestowed upon a comparison of all the least discordant drawings, and the punctilious accuracy of his protracted discussions, would be little appreciated from so brief a sketch of them as can be attempted here. He was himself so little pleased with the result as to express an opinion that the only safe inference from the oppositions of 1862 and 1864 is, that the art of drawing celestial objects is at much too low a pitch to justify accurate deductions as to their physical character. And this, though it looks like the language of disappointment, and is hardly reconcileable with the striking agreement which he often remarks between the drawings of different observers, or the same observer at different times, seems to have been his deliberate impression. He ascribes the variations in part to the differences of presentation and perspective, in part to faulty delineation; and while he admits that atmospheric condensations may have occasioned small apparent changes, he thinks on the whole that they are evidences of the unsteadiness of our air, leaving almost always an uncertainty as to the minuter spots and shadings, and a want of confidence in the correctness of one's own delineation. The discrepancies among his 412 designs are so "enormous" that no one would believe that they were intended for the same body. These differences arose, however, in part from natural causes. Even in the most favourable case, the spots are only seen with any distinctness or in their true form in the centre of the disc; those lying near the limb being greatly foreshortened and not recognisable in their real shape; and this difficulty is very considerably enhanced by the imperfect transparency of the planet's atmosphere and its frequently strongly illuminated precipitations. The inclination of the axis may vary its position at different times about 60° as regards the spectator, and consequently different oppositions bring before him entirely different features in that central position where alone they can be well observed or drawn.

* It is much to be regretted that only a part of the drawings of this great observer have as yet been published in *fac-simile*. Those given in the Monthly Notices (XXV., 225) omit, as Kaiser remarks, some of the most curious presentations of the globe; and the reproduction of others by Proctor does not profess minute accuracy.

And to these sources of difficulty it might, we think, have been added that, in consequence probably of our study of geography from projections of the globe in which the effect of perspective is designedly counteracted as much as possible, we are apt to have a very defective idea of the amount of apparent distortion which it occasions towards the edges of the visible hemisphere. But even when all this has been allowed for, we find, the professor tells us—nor indeed do we need opportunities as extensive as his to convince ourselves of it—that the differences are much too great to be altogether thus explained; and he concludes that the more conspicuous ones are errors in representation. If there is occasional agreement as to the forms, there is still much risk in referring them to the same object, until it has been ascertained by computation that the presentation of the globe towards the spectators was nearly the same. Fortunately, during any given opposition, the position of the planet's axis shifts but little, and in other oppositions the same presentation recurs from time to time; but instead of the correspondence naturally anticipated, the differences are for the most part, as he expresses it, "enormous." And yet amongst them all, coincidences come to the surface, too remarkable to admit the idea of fortuitous resemblance; and we must suppose that many who have taken pencil in hand have not been sufficiently careful as to form and shading, but have followed arbitrary and perhaps very mistaken impressions, from which nothing but absurd and absolutely contradictory inferences of a physical nature could be drawn.

(*To be continued.*)

THE ADMIRALTY CHARTS OF THE PACIFIC, ATLANTIC, AND INDIAN OCEANS *

THESE charts have been compiled by Captains Evans and Hull, of the Hydrographic Departments of the Admiralty, from Maury's pilot charts, Fitzroy's and Fergusson's wind charts, charts issued by foreign Governments, and from the works of Dovè, Neumayer, Buchan, and documents in the Hydrographic Office of the Admiralty. They show for the four seasons the pressure, winds, and temperature over the parts of the globe covered by the sea. January, February, and March are properly grouped together into one season, these being the three coldest months as regards the oceans in the northern, and the three warmest in the southern hemisphere.

The most important piece of new work in these charts is the "isobars," or lines of equal barometrical pressure, which are given for the seasons. These isobars for the sea, taken in connection with Buchan's isobars published in 1868, may be regarded as the first approximation to a complete representation of the earth's atmosphere over both land and sea. We have minutely examined these isobars, comparing them with the large amount of new information collected during the past five years from many places situated on the coasts of the continents, or in islands scattered over the ocean, and can come to only one conclusion, viz., that the greatest care has been taken in their construction. Among the very few cases to which slight exception might be taken is the isobar of 29·7 in. of July, August, and September, drawn to southwards of Japan, which observations do not appear to warrant. It should also be pointed out that a serious omission has been made in not stating how the ship barometric observations were reduced to the mean pressures from which the isobars have been drawn.

We are now in a position to draw one or two general conclusions of great importance regarding the distribution of atmospheric pressure over the ocean. In the ocean, to westwards of each of the continents, there is at all seasons an area, or patch, of high pressure, from 0·10 inch to 0·30 inch higher than is found on the coast westward of which it lies. The distance of the centre of the space of high pressure from the coast varies from 20° to 35° of longitude, the average distance being nearly 30°. The position of the centre of the space varies from about 22° to 35° north or south latitude, or stating it roughly it lies about the zones of the tropics. In these spaces the absolute pressure is greatest during the winter months of the respective hemispheres—a condition of things probably due to the fact that during the winter season of the northern hemisphere the great mass of the earth's atmosphere is disposed about the tropic of Cancer, and during the winter season of the southern hemisphere, about the tropic of Capricorn. The position and shape of the isobars seem to be largely determined by that of the continents adjoining. Thus the rounded form of the southern portion of North America, the bending eastward of the west coast of South America from Payta to Arica, and the form of the north-western part of Africa and its "lie" from S.W. to N.E. are all more or less impressed on the isobars bounding the contiguous spaces of high pressures. These spaces are less prominently marked west of those continents which have the least breadth in lat. 30°; thus the area of high pressure is less marked west of the Cape than it is west of Australia, and still less than to the west of North America. The isobars are much farther apart on the western than on the eastern side of these areas of high pressure; indeed in many cases they are as it were drawn out so as almost to reach the continent lying to westward; and in some cases there is even a tendency towards, or the actual appearance of, secondary areas of high pressure to eastwards of continental masses. This is most distinctly seen to eastward of Australia.

We have dwelt thus particularly on these spaces of high pressures because of their importance in atmospheric physics, but more especially because of their vital connection with prevailing winds and the general circulation of the atmosphere. Out of these high pressures, the wind blows in all directions anti-cyclonically in accordance with the well-known "Buys Ballot's Law of the Winds," of which relation the wind charts before us afford abundant confirmation. Keeping this relation between wind and pressure in view, we have presented in these high pressures the proximate causes of the prevailing winds over the greater portion of the ocean; and through the prevailing winds, the drift currents and other of the surface-currents of the sea; and thereby the anomalous distribution of the temperature of the sea as seen in the Chile, Guinea, and other currents, and the peculiar climates of the coasts past which these currents flow.

The small area of high pressure to the east of Australia may be singled out as perhaps the most interesting of the new facts in the charts. During winter the winds along the east and south of Australia blow inwards upon the interior of that continent, whereas in New Zealand the prevailing winds at the same season are north-westerly and westerly, the directions being thus generally opposite on these two coasts facing each other. The space of high pressure between gives a ready explanation of the direction of these winds, as well as of the heavier rainfall on the west of the South Island of New Zealand as compared with that of the North Island, and of the south-east as compared with the south-west of Victoria.

Like praise cannot be given to the charts of the isothermals of air for January, April, July, and October. In the October chart, the isothermal of 60° cuts the east coast of South America near lat. 27°; now at Monte Video, the mean temperature of October is 61·2°, at Buenos Ayres 61·3°, and at Bahia Blanca, in 38°·4 S. lat. 59°·7; that is, the isothermal of 60° should cut the South American coast 11° of latitude farther to the south. The January isothermal of 60° is drawn passing through New

* "Wind and Current Charts for the Pacific, Atlantic, and Indian Oceans," published at the Admiralty, October 1872, under the superintendence of Rear-Admiral G. H. Richards, C.B., F.R.S., Hydrographer.

Zealand near lat. 40°, and the isothermal of 50° near Dunedin; now the mean temperature of January at Southland situated at the extreme south of New Zealand is 57°·6, and at Duned in (550 ft. high) 57°·5; in other words, the isothermal of 60° and not that of 50° ought to pass near Dunedin. Dr. Hector's meteorological reports during the past seven years place this beyond all doubt, and it is unfortunate that the summer climate of this important colony of Great Britain should have been so misrepresented as to appear to be colder than that of Iceland, and altogether insufficient for the ripening of wheat, barley, and other cereals. The July isothermal of 90° is represented as having its eastern extension at the entrance to the Persian Gulf in 57° E. long. Now Murray Thomson's and Blandford's meteorological reports show that the isothermal of 90° extends eastward to about 77° E. long, so as to embrace the Punjaub and the upper tributaries of the Ganges to the west, being thus 20° farther east than is represented on the chart.

The truth is, that, excepting for the months of January and July, there have been no isothermal charts of the months for the whole globe yet published which do not contain many gross errors similar to those we have pointed out. The time is surely not far off when a committee of the British Association, or some competent authority, will take up this subject, and give us a set of new isothermal lines laid down from all data which the great expansion meteorology has received of late years has made available.

The two charts showing the isothermals of the sea for the extreme months, February and August, and the chart showing the surface currents of the ocean, are very valuable. A supplementary chart showing the currents south and east of Asia during the monsoon season is also given. We should suggest for the second edition of the Charts, that charts of the surface currents for both February and August should be given for the whole globe, it being only thus that these important aids to navigation can be adequately presented.

It was pointed out in NATURE some years ago that the prevailing winds and surface currents of the Atlantic are all but absolutely coincident. These Charts enable us now to extend the remark to the prevailing winds and surface currents over all the oceans. Keeping out of view the deep-water currents of the sea to which Carpenter has given so much attention, it is now placed beyond all doubt that it is to the winds we must look as the prime movers of oceanic currents.

MR. GARROD'S NEW CLASSIFICATION OF BIRDS

AT the scientific meeting of the Zoological Society, on Tuesday, February 3, Mr. A. H. Garrod introduced a new Classification of Birds, based mainly on the disposition of their muscles and other soft parts. The following is an abstract of his paper:—

The osteology of birds, judging from the unsatisfactory state of their classification in the present day, is not sufficient in itself as a basis for distinguishing the mutual relations of the different families and genera; and as the peculiarities in the soft parts are very constant, they deserve more consideration than they have hitherto received. The researches of Hunter, Nitzsch, Macgillivray, Owen, and others, have brought to light many facts in visceral anatomy and pterylosis, all of which are of great value in classification. Sundevall is the only ornithologist who seems to have made any generalisations respecting myology, and these have an important bearing on the subject.

My method of work, Mr. Garrod went on to say, has been the following:—After having carefully dissected a few birds that are known to be but distantly related, a comparison of the notes on the individuals examined showed that there were important myological differences between them. Further dissection of species related more or less intimately, indicated broadly the relative value of the peculiarities that were found, when taken in connection with the most approved classification of the present day; and as observations became more numerous the relative importance of the facts observed was more easy to estimate. The muscles which have, on account of their marked tendency to vary in the class Aves, attracted the most of my attention, are all situated in the thigh, and they are five in number: (1) the *femoro-caudal*, which runs from the linea aspera of the femur, near its head, to the sides of the tail vertebræ; (2) the *accessory femoro-caudal*, which runs parallel to the last, and behind it, from below the femur-head to the ischium; (3) the *semitendinosus*, which crosses the first-named muscle superficially, and arises from the lower part of the ischium, to be inserted into the inner side of the tibia-head; (4) the *accessory semitendinosus*, which arises from the distal end of the linea aspera, and joins the fibres of its larger namesake obliquely just before their insertion; (5) the *ambiens*, that peculiar slender muscle which arises from just above the acetabulum, and after running obliquely through the ligamentum patellæ, joins the tendon of the flexor perforatus digitorum. My observations on these five muscles have been made on more than 500 species of birds, including more than 600 specimens, and the results are recorded in a tabular form, in a paper now in course of publication in this Society's Proceedings. For the present, no more attention need be paid to these muscles themselves, but only their presence or absence considered; therefore, to simplify description, a myological formula will be employed which indicates all the facts required in a very precise manner. Calling the first four of the above-mentioned muscles, A B X and Y, respectively, and omitting from the formula thus based, the symbol or symbols which represent any that are deficient, it is clear that a bird, like the common fowl for example, which possesses them all, would be represented by ABXY; and the eagle, in which the femoro-caudal is alone present, by A; whilst the sparrow, which only wants the accessory femoro-caudal, must have the formula A X Y; and the duck, which only lacks the accessory semitendinosus, is represented by A B X. By this means it is possible to make important statements respecting the myology of any bird in a very concise form, which gives great facility towards the comparison of different species. It must here be mentioned that individuals of a species and species of a genus do not vary among themselves in the muscles under consideration. The following table gives the myological formula of the different families of birds, as far as my dissections enable me to go, the only important types omitted being Eurypyga, Psophia, Todus, and Bucco. They are arranged in an order to be subsequently explained, and the presence or absence of the ambiens-muscle is indicated by + or — after each formula:—

TABLE I.

Struthionidæ B X Y +	I.
Casuariidæ { A B X Y — B X Y —	*Picidæ* { *A X Y* — *A X* —
Tinamidæ A B X Y +	
Palamedeidæ A B X Y +	*Ramphastidæ A X Y* —
Gallinæ { A B X Y +	*Capitonidæ A X Y* —
(excl. Turnix) B X Y +	*Upupidæ A X Y* —
Rallidæ A B X Y +	*Bucerotidæ A X Y* —
Otididæ B X Y +	*Alcedinidæ A X* —
(Incl. Cariama and Serpentarius.)	
Phœnicopteridæ B X Y +	
Musophagidæ A B X Y +	II.
Centropinæ A B X Y +	
Cuculinæ A X Y +	*Passeres* { *A X Y* —
Psittaci A X Y ±	*A X* —
Anatidæ A B X +	*Trogonidæ A X* —

Spheniscidæ A B X +	*Meropidæ A X Y —*
Colymbidæ A B X +	*Galbulidæ* { *A X Y —* / *A X —*
Podicipidæ B X —	
Procellariidæ { A B X Y + / A B X + / A X +	*Caprimulgidæ A X Y —*
	Steatornithidæ X Y —
	Coraciidæ A X Y —
Ciconiidæ A X Y +	*Momotidæ A X Y —*
Cathartidæ { A X Y + / X Y +	
Ardeidæ { A X Y — / X Y —	III.
Phalacrocoridæ A X +	*Cypselidæ A —*
Phaethontidæ A X Y +	*Trochilidæ A —*
Fregatidæ A +	
Falconidæ A +	
Strigidæ A —	
Gruidæ A B X Y +	
Charadriidæ { A B X Y + / B X Y +	
Laridæ A X Y +	
Alcidæ A B X —	
Columbæ A B X Y ±	

On looking at the formulæ in the above table it will be seen that there is a tendency to similarity in those that are placed in juxtaposition; and further, that the presence or absence of the ambiens muscle, indicated by the signs + and —, is more constant than the other characters. Thus, among the *Cuculidæ*, the *Picidæ* and *Ardeidæ*, the ambiens does not vary whilst one or other of the rest is inconstant. There are more reasons than the above for assigning primary importance to the ambiens muscle, which depend on the nature of the tip of the oil-gland and the cæca of the intestine. For, with but few exceptions, those birds which possess the ambiens muscle have cæca to the colon and a tuft of feathers on the oil-gland, whilst those in which the ambiens muscle is absent, have either cæca and a nude oil-gland, or a tufted oil-gland and no cæca. The true relationship of the exceptions is, however, indicated by other collateral characters, the most important of which is the presence or absence of the accessory femoro-caudal (B); that muscle being never found in those birds in which the ambiens is always absent, so that any bird with it developed, is certainly related to those in which the ambiens is present. These facts lead me to propose the division of the class Aves into two primary sub-classes,—the *Homalogonati*,* in which the ambiens is present, and the *Anomalogonati*† in which it is always absent. The former of these are printed in the above table in Roman letters, the latter in italics.

It may be asked, why, on the above principles, are the Ardeidæ and the Strigidæ placed with the Homalogonatous birds, especially as the latter have a nude oil-gland? The position of the latter of these two families is no doubt uncertain, but the sum of characters is in favour of the places assigned to it.

Next, respecting the most important sub-divisions of the Homalogonatous, and the Anomalogonatous birds. Taking the latter first, because they are fewer in number, and more clearly separable, they are found to fall naturally into three well-defined orders:—(1) those in which the oil-gland is nude and the cæca of the intestine present; (2) those in which the oil-gland is tufted and the cæca are absent; and (3) those in which the oil gland is nude and the cæca are absent. These three sections of the Anomalogonatous birds are indicated in Table I. by the corresponding numbers, the Picidæ heading the first, the Passeres the second, and the third comprising the Macrochires only. To most ornithologists the not unreasonableness of this arrangement will be fairly apparent.

* With the knee normal; that is, with the ambiens crossing it.
† With the knee abnormal; that is, with the ambiens deficient.

" 1. Momotinæ
" 3. Todinæ (?)

Order III. *CYPSELIFORMES*

Family 1. *Macrochires*
Sub-fam. 1. Cypselinæ
" 2. Trochilinæ

The Homalogonatous birds must be divided upon a different basis, and their myological formulæ here come into service. Before going further it is necessary to show that the habits of the species are not the cause of their myological peculiarities in most cases, though probably in some they do affect them. The Heron and the Swallow have the same formula, and yet how different their habits? the same may be said of the Owls and the Swifts; the Kaleege and the Flamingo. The Auk and Guillemot, however, are most probably but distantly related to the Ducks and Penguins if the peculiarity in the nasal bones has the importance that I assign to it; nevertheless, the muscles of their legs agree more with them, than with the other Schizorhinal birds. By a glance at Table II., the manner in which the Homalogonati may be best subdivided according to the facts that I have been able to bring forward, may be obtained. Commencing with the orders, the *Galliformes* include all those birds related to the Fowls; and notwithstanding the high opinions to the contrary, I cannot feel justified in separating the Struthious birds away from this group. It is not difficult, after having seen the formula of the Musophagidæ and Cuculidæ (Table I.), to recognise that these families have nothing to do with the Anomalogonatous birds, although they are peculiar in the former having no cæca, and the latter a nude oil-gland. The Psittaci also cannot be placed anywhere else.

The *Anseriformes* all agree, with the exception of the Storm-Petrels, which are also otherwise difficult to place, in wanting the accessory semitendinosus (Y), and in having the great pectoral muscle very elongate. The whole family of petrels are exceptions in this point also, and may have to be put in the next order, amongst the Ciconiiformes.

The *Ciconiiformes* include amongst them the Accipitres, but myology is in no point more clear than with regard to the unnaturalness of that family as at present defined. Every Eagle, Hawk, true Vulture, and Owl, has for formula A. The Secretary Bird, which is generally placed with them, is represented by B X Y; from which it is seen to be as different from them as it can possibly be. This shows that the position of *Serpentarius* must be changed; that it is not a raptorial bird at all; and that, as in formula and general appearance it resembles *Cariama*, it must be placed near it and the Bustards. Similar arguments indicate that the Cathartidæ are not true Accipitrine birds, but must form an independent family, though still in the same order as the Falcons.

The *Charadriiformes* all possess the peculiar nasal arrangement which I have termed Schizorhinal. The *Turnicidæ* and *Parridæ* are included with the *Limicolæ*, and the *Pteroclidæ* with the *Columbæ*.

The justification of many of the smaller divisions of the above orders will be seen by comparing the myological formulæ, and by a review of the osteological, pterylographical, and visceral arrangement of each.

In any attempt at classification on new facts, it must be remembered that there must be great inequality in the importance of the results arrived at in each order as freshly defined. In one family there may be a uniformity in a particular structure which is greater than could possibly have been expected; whilst in another the previously constant character may be one of the most uncertain. For instance, the left carotid artery is alone present in all the Passerine birds that have ever been examined: but amongst the Bustards the Great Bustard has two, Denham's only the right, and *Tetrax* only the left. Therefore it is not to be wondered at that myology is equally uncertain in its indications sometimes, though on other occasions its teaching is most decided. In the above attempt at a new arrangement, it has been my endeavour to bring forward the results of observations made during a considerable time, with the facts obtained from previous work always kept prominently in the foreground.

NOTES

In a Congregation held at Oxford on Feb. 10, Prof. H. Smith introduced a statute providing that the certificate of the examiners appointed under the authority of the Delegates of the Examination of Schools, when given in Greek, Latin, and Elementary Mathematics, be accepted in lieu of Responsions. He represented that in Mathematics the standard would be higher than in Responsions; in Greek and Latin it would be equal, owing to the requirement of translation of "unseen pieces." The candidate would also have to pass in some other subject. It was therefore inconceivable that the idle should select the Schools Examination as the easier. The standard would be kept up by the employment of the same class of examiners as in other University examination. The preamble of the statute was accepted.

Dr H. Alleyne Nicholson, Professor of Natural History in University College, Toronto, has been appointed to the Professorship of Zoology in the Royal College of Science, Dublin, vacant by the resignation of Dr. Traquair. Prof. Nicholson is known as the author of many papers on the Graptolites, and as a writer of several text-books of zoology.

The Smith's Mathematical Prizes have been adjudged to Mr. Walter W. R. Ball, second wrangler, 1874, and Mr. George Stuart, B.A., Emmanuel College, Cambridge, bracketed fourth wrangler, 1874.

A meeting of those who have signified their interest in the formation of the new Physical Society will be held on the 14th inst., at 3 o'clock P.M., in the Physical Laboratory, South Kensington.

A general meeting of the Provisional Committee for the establishment of the Scientific Societies Club was held on Jan. 29 at the Westminster Palace Hotel, when an organising committee was appointed with a view to the early opening of the club. The number of "original members" is nearly complete, 231 gentlemen having given in their names. Among the Provisional Committee we notice the names of Dr. Gladstone, Prof. Lawson, and Prof. Morris, and others known to Science.

At the meeting of the Paris Academy of Sciences on Feb. 2 the place of Correspondent of the Astronomical Section, left vacant by the election of Sir George Airy to a Foreign Associateship, was filled up. M. Tisserand obtained 25 votes and M. Stéphan 23. The former was therefore elected. At the same meeting the Academy, sitting in secret committee, received the report of the committee appointed to select candidates for the Chair of Embryology at the College of France. M. Balbiani was placed first, M. Gerbe second. The election was announced for the 9th inst.

WE have just received from Mr. Gerard Krefft the cast of a fossil specimen of extreme interest. It is that of one of the teeth of an extinct species of *Ceratodus* found with the usual *Diprotodon* remains in the alluvial deposits of the Darling Downs district of Queensland. This able naturalist has named the fish indicated by this fossil in honour of the present Colonial Secretary of Queensland, *Ceratodus palmeri*. It is larger than the corresponding tooth—the left upper dental plate—of *C. forsteri*, the enamel being rather coarser and the surface more undulated than that of Forster's fish. In the specimen under consideration, three of the prongs are perfect, being three-fourths of an inch in width. Mr. Krefft mentions that the existing fish is called "Jeevine," and not "Barramundi;" also that it never goes ashore, and is not caught, as supposed by some, with hooks baited with frogs.

THE *Academy* has been favoured by Dr. Kirk with the following private telegram, which he received from Brigadier-General Schneider, C.B., Her Britannic Majesty's political Resident at Aden, with reference to the news of the death of Livingstone. Dr. Kirk considered that the details given in the telegram as published concerning Livingstone's death and the embalming of his body presented so many doubtful points which required clearing up, that he was anxious to ascertain whether Cameron had convinced himself of the accuracy of these reports by personal examination of the messengers who, it is said, preceded Livingstone's dead body to Unyanyembe, and among whom was Chumah, his servant; or whether the reports had come to his ear, before Chumah himself reached Unyanyembe, in the usual untrustworthy and exaggerated native manner. He therefore telegraphed to General Schneider; but, as will be seen by the reply from General Schneider, it cannot be ascertained at present whether Cameron actually saw Chumah. The evil tidings may have preceded him by some days; and there is nothing for it but to wait the receipt of Cameron's written advice:—"General Schneider to Dr. Kirk.—Aden February 2, 5.15 P.M.—Captain Prideaux merely says Chumah went ahead and gave intelligence to Cameron."

THERE has been instituted by the French Government, under the Minister of Public Instruction, a Commission of Scientific and Literary Voyages and Missions. The object of the Commission, we learn from *Les Mondes*, is (1) to discover what are the most useful scientific and literary enterprises; (2) to examine the projected voyages and missions proposed to the Minister; (3) to study the programmes of these missions, to give detailed instructions to those who undertake them, and to carry on correspondence, if necessary, during the voyage; (4) to examine, on their return, the works on which the voyagers have reported, and prepare their publication in a record of Missions, when that is founded; (5) to name to the Minister such voyagers as may be worthy of honourable reward after the completion of their enterprise; (6) to appeal to the various administrations to concentrate on certain enterprises all the resources at the disposal of the state. The Under-Secretary of State is President of the Commission, and M. Beulé Vice-President; while, among the members are, MM. Felix Ravaisson, Conservator of the Louvre Museum, Leon Renier, Chevreul, Milne-Edwards, D'Avezac, President of the French Geographical Society.

THE *Paris Journal* gives a curious account of an hotel situated in the *Rue des Petites Ecuries*, which has a *clientèle* of living phenomena. It is an hotel of the lowest order, which was fitted up by a French barman for housing extraordinary creatures. The *homme chien* and his son Fedor lived there for some time. The giant of Folies Bergeres (8 ft.) dwelt there. He was an intimate friend of a dwarf whom he carried in his arms every evening, when taking his daily promenade after dark. There are also a good many acrobats and lion-tamers admitted into the house. Mdlle. Christine, the double sisters, were not a lodger; they had an agent of their own, an Englishman. Most of these curious specimens of humanity are placed under the direction of the hotel-keeper, who procures engagements for them at certain prices, according to their *demerits*, and directs them either to some of the minor theatres, concert-halls, or to the booths erected at suburban fairs. A *Table d'hote* of the Petites Ecuries Hotel, where all these strange creatures come together, is the most extraordinary sight in the whole town.

THE sale of several works on the book-stalls at railway-stations has been prohibited by the Minister of the Interior. Amongst these we notice "Les Ballons du Siege," by M. W. de Fonvielle, who, as it is known, escaped from Paris in a balloon during the investment of Paris, and delivered lectures in London. M. W. de Fonvielle, who was just returning from London when the prohibition was issued, has written to the minister in order to ascertain the real facts of that extraordinary decision.

DR. A. ERNST prints (unfortunately in Spanish) under the title "La fécula y las plantas farináceas del nuevo mundo," a list of 100 plants of the New World which yield starch, with detailed accounts of the more important ones.

IN the discussion which followed, Sir Bartle Frere's address, at the opening of the African Section of the Society of Arts, Mr. Hyde Clarke read a letter from Lieut. Maurice, Private Secretary to Sir Garnet Wolseley, dated "Head Quarters, Yancoomassie," from which we take the following extract; it may prove of some interest to students of the Science of language:—"A somewhat curious piece of word-coining, which has fallen under our notice here, may interest you in connection with the broader aspects of the subject of which you write. The Ashantees having experience of our rockets only as they come to them in destructive form at the end of their journey, call them by the sound they make, 'Schou-schou,' or something of the kind. The Fantees, on the other hand, adopt bodily into their Language our own names for those things which they have not seen before. Thus to the Houssa or the Fantee, in speaking to one another, our rockets are named rockets, while their enemies call them schou-schou. It is possible that as war has not been in savage times an uncommon condition of mankind, analogous causes for different names having been adopted by different nations may have been not unfrequent in the past."

THE Council of the Statistical Society have founded a bronze medal, under the title of "The Howard Medal," to be presented to the author of the best essay on some subject in "Social Statistics" a preference being given to those topics which Howard himself investigated, and illustrated by his labours and writings. The title of the Essay to which the Medal will be awarded in November 1874, is as follows:—"The state of Prisons, and the condition and treatment of Prisoners, in the Prisons of England and Wales, during the last half of the eighteenth century, as set forth in Howard's "State of Prisons," and work on 'Lazarettos.'" The Essays must be sent to the Assistant Secretary of the Society on or before September 30. The competition is open to any competitor, providing the Essay be written in the English language.

WE called attention last week to the course taken by the Perthshire Society of Natural Science, in reference to the present election of Members of Parliament. The Society sent questions to the candidates for the City and County of Perth, relating to the appointment of a responsible Minister of Education, to State help for Science, and to the promotion of scientific exploration expeditions, such as that of an Arctic expedition. The Liberal candidates sent no reply; the Conservative candidates sent favourable answers. The following is the reply of Sir William Stirling Maxwell, the Conservative candidate for the County of Perth:—

"In reply to your letter, I beg to say that I have long been of opinion that the Existing Education Department, and all our Public and Literary Institutions should be placed under the general supervision of a responsible Minister. In Parliament I was generally inclined to favour the expenditure of money for scientific objects when the Government thought proper to sanction them; and an Arctic expedition, and various researches, unremunerative in a pecuniary sense, might fairly fall into the list of such objects."

IN June last year Prof. O. C. Marsh, the discoverer of *Dinoceras and Brontotherium*, started on a five months' geological expedition to the Rocky Mountain regions and the Pacific coast, to study, as he had done on previous occasions, the Cretaceous and Tertiary formations, which are there so rich in vertebrate remains. From Fort McPherson, Nebraska, they proceeded to Niobrara under the escort of two companies of United States cavalry, which were indispensable on account of the hostile position of the Indian tribes. Among the other places visited were Fort Bridger, Wyoming; Idaho and Oregon; Colorado and Kansas. The expedition was very successful, and the collections procured were large, containing many new forms. It is much to be regretted that no English geologists have accompanied Prof. Marsh, as most of the fossils peculiar to the regions he is exploring, are quite unknown in this country, except from descriptions.

THERE will be held at Christ Church, Oxford, on Saturday February 28, an election to a Junior Studentship in Physical Science, tenable for five years from the day of election. It will be of the annual value either (1) of 100*l*. (inclusive of an allowance for room rent), if the Governing Body shall so determine; or (2) of 85*l*. (also inclusive of an allowance for room rent), which sum may be raised to the larger sum above-named after the completion of one year's residence, if the Governing Body shall so determine. Candidates must call on the Dean on Wednesday, February 18, at 1.30 P.M. The examination will follow at 2 P.M. Candidates must not have exceeded the age of 20 on the 1st of January last, and must produce certificates both of the day of their birth, and of good character. Papers will be set in Chemistry, Physics, and Biology; but candidates will not be expected to offer themselves for examination in all these subjects.

PROF. COPE has recently explored the beds of the late tertiary formation, called Pliocene, as it occurs in north-east Colorado. He discovered twenty-one species of vertebrata, mostly mammals, of which ten were new to science. Four are *carnivora*, six horses, four camels, two rhinoceroses, one a mastodon, &c. The most important anatomical results attained are that all the horses of the formation belong to the three-toed type, and that the camels possess a full series of upper incisor teeth. The discovery of a mastodon, of the *M. ohioticus* type, constitutes an important addition to the fauna. One of the horses is distinguished by its large head and slender legs, much longer than in the common horse. A full account of these results will shortly appear in the report of Dr. Hayden's Geological Survey of Colorado.

THE additions to the Zoological Society's Gardens during the past week include a Suricate (*Suricata zenic*) from S. Africa and a West African Python (*Python sebæ*), presented by Mr. J. H. Coonley; a Feline Douracouli (*Nyctipithecus felinus*) from Brazil, presented by Mr. G. Hollis; a common Kingfisher (*Alcedo ispida*), British, presented by Mr. A. Yates; a Collared Fruit Bat (*Cynonycteris collaris*), an Axis Deer (*Cervus axis*), and a Molucca Deer (*C. moluccensis*), born in the Gardens; two De Fillippi's Meadow Starlings (*Sturnella de filippi*) from Rio de la Plata, received in exchange.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, Jan. 22.—"On the Physiological Action of the poison of *Naia tripudians* and other Indian Venomous Snakes," II., by Drs. Brunton and Fayrer.

The results of these investigations show that the poison of the cobra is similar in its action to that of Ophiophagus, Bungarus, and other Colubrine snakes, whilst that of Daboia is similar to the virus of Echis, the Trimeresuri, and other viperine snakes, the chief difference between them being the greater tendency in the viperine poison to cause hœmorrhage or more severe local symptoms. The blood of animals killed by the viperine snakes generally remains fluid after death, whilst that of animals killed by colubrine snakes form a firm coagulum.

The conditions caused by the action of the poison are illustrated by the symptoms manifested by man and the lower animals. The Cobra, Ophiophagus Hydrophidæ, and Bungarus are all very deadly. The Viperine Daboia, and Echis are scarcely less so, whilst the Indian Crotalidæ, such as the Trimeresuri, are much less so. A series of experiments is detailed which illustrate the physiological action of the virus on the nervous system, the muscles, the blood, the respiration, the circulation, and the function of excretion, and also the mode in which death is produced.

The fatal action is shown to be due (1) to arrest of the respiration by paralysis of the muscular apparatus, by which that function is carried on. (2) Or by rapid arrest of the heart's action, in cases where the poison has found direct entry by a vein, *e.g.* the ju ular. In such, death is almost instantaneous, and the heart is found to have ceased to beat when in systole. The physiological import of this is very interesting and important, and it was demonstrated by Dr. Brunton, who explained its probable mode of action in certain ganglionic centres in the heart; a subject which gave rise to some discussion; (3) or death may be due to a combination of arrest of respiration and of the heart's action; (4) or it may be due where the quantity of poison is small, or its quality less active, to secondary causes of the nature of other septicæmia, a purely pathological question not discussed.

The mode in which paralysis of respiration (the ordinary form of death) is induced, has been most thoroughly investigated, and it may be said that the question is now settled.

The virus absorbed into the blood either by inoculation into the areolar tissue, or by application to a mucous membrane, affects the cerebro-spinal nerve-centres, the nerves and their peripheral distribution, more especially of the motor nerves. The sensory nerves are less and later affected, and the intelligence generally latest of all, and slightly. The complete loss of it, and the convulsions which precede death, is mainly caused by the circulation of venous blood, the result of the impeded respiration.

Muscular force and co-ordination are gradually lost; paralysis and asphyxia being the evidence thereof. In ordinary cases, the heart goes on beating vigorously long after apparent death, and with artificial respiration, may be kept up for many hours.

The investigations recorded, were made with cobra and daboia poison, sent to England from Bengal in the dried state, a condition in which it resembles gum arabic, and its activity is great. The animals experimented on were dogs, cats, rabbits, guinea-pigs, fowls, pigeons, small birds, frogs. Its action on all these, and the mode in which functions and tissues are affected, are recorded in detail, as well as the extent to which the action of the poison is modified when introduced through different channels.

It has now been clearly shown that the poison acts, when introduced into the stomach, or when applied to a mucous or serous membrane. The idea that it was only effective when injected directly into the blood, is erroneous. It is, no doubt, more certainly and rapidly fatal when it enters the blood direct.

It is also shown that it may be eliminated by the excreting organs, and that there is, therefore, reason to hope that life may be saved if it can be artificially sustained long enough to admit of complete elimination being accomplished, as in the case of curare poisoning; but from the more complex action of the cobra poison this remains a subject of doubt.

By artificial respiration the circulation has been maintained, both here and in India, by Dr. Ewart and Mr. Richards, for many hours; and in one case, after complete paralysis had occurred, symptoms of reaction and elimination were obtained; but no

complete recovery has yet occurred. The doubt still remains whether the nervous system that has sustained so much damage, is capable of ever resuming its functions, even though elimination be complete.

The so-called antidotes appear to be inert; all that have been submitted to trial, including the intra-venous injection of ammonia, have failed to have any satisfactory effect. Artificial respiration has certainly prolonged life, and partial recovery has followed, but no life has actually been saved by it.

The microscopic appearances of the blood are described, but no very remarkable change was observed beyond crenation of the corpuscles or diminished aggregation into rouleaux. Chemical examination of the blood and its gases is still needed and further analysis of the poison is desirable.

It is shown that the activity of the poison is scarcely impaired by drying, excepting perhaps so far as regards its *local* action.

Dilution with water, glycerine, liq. ammoniæ, and liq. potassæ did not destroy its activity, nor did coagulation by boiling in the ordinary way. The boiling for half-an-hour under a temperature of 102° C. seemed to destroy the activity of one specimen which was injected into a bird.

The poison acts on all life, on the lower and higher vertebrata, the invertebrata, and even on vegetable life; for it retards, although it may not arrest the germination of seeds. But it acts most vigorously on the warm-blooded animals.

The most remarkable fact connected with it is that it has little or no effect on poisonous snakes. They can neither poison themselves nor their congeners; or if at all, very slightly so, whilst the poison acts rapidly and fatally on innocent snakes, lizards, fish, and mollusca.

With reference to the means of preventing death, it may be said that those that mechanically prevent the entry of the poison into the circulation by means of the ligature, excision, or cautery are the most reliable, but that they are only so when applied immediately.

No means that offer any hope of benefit should be neglected, and it is possible that stimulants such as alcohol and ammonia may be useful; and in some cases, where the poisoning has been severe but not fatal, do good and even determine recovery where death would have otherwise resulted. The so-called antidotes, however, beyond any actions of this kind that they may possess, are apparently quite inert.

Transfusion of blood is alluded to, but the experiments hitherto proposed have not met with success. A more perfect way of accomplishing it may be more successful.

Zoological Society, Feb. 3.—Dr. E. Hamilton, vice-president, in the chair. The secretary read a report on the additions that had been made to the society's menagerie during the month of January, 1874, amongst which were specially noticed a female Water-Deer (*Hydropotes inermis*), a pair of Pink-headed Ducks (*Anas caryophyllacea*), and a Dusky Monkey (*Semnopithecus obscurus*), acquired by purchase, and two Vulturine Guinea-fowls (*Numida vulturina*), presented by Dr. J. Kirk.—An extract was read from a letter addressed to the secretary by Mr. Luigi M. L. Albertis, containing an account of a new species of kangaroo, of which he had lately obtained a living specimen from New Guinea, and which he had proposed to call *Halmaturus luctuosus*.—Dr. Cobbold communicated the second part of a series of papers entitled "Notes on the Entozoa;" being observations based on the examination of rare or otherwise valuable specimens contributed at intervals by Messrs. Charles Darwin, Robert Swinhoe, Charles W. Devis, the late Dr. W. C. Pechey, Dr. Murie, and others.—Mr. Garrod read a paper in which he proposed a new classification of birds, details of which will be found in another page.

Chemical Society, Feb. 5.—Prof. Odling, F.R.S., president, in the chair.—The secretary read a preliminary notice on the action of benzyl chloride on the camphor of the Lauraceæ (*Laurus camphora*), by Dr. D. Tommasi.—Dr. C. R. A. Wright had a paper on the Isomeric Terpenes and their derivatives: Part III. On the essential oils of wormwood and citronelle; being a detailed account of his experiments on these substances, a preliminary notice of which was communicated to the society some time since.—The other communications were a preliminary notice on the perbromates, by M. M. Pattison Muir, F.R.S.E.; and on the coals from Cape Breton, their cokes and ashes, with some comparative analyses, by Henry How, D.C.L. The latter paper giving the amount of coke produced by slow and quick coking, from the main seam coal of Sydney mine, Nova Scotia, and the Lingan coal, also analyses of the ashes left by these coals.

Royal Microscopical Society, Feb. 4.—Anniversary meeting.—Chas. Brooke, F.R.S., president, in the chair. The report of the council and the treasurer's statement of accounts were submitted and adopted, and the officers and council for the ensuing year were elected. The president delivered an address, and concluded with obituary notice of Fellows deceased since the last annual meeting. The following gentlemen were elected as officers and council. President—Chas. Brooke, F.R.S. Vice-Presidents—Dr. Braithwaite, F.L.S.; J. Millar, F.L.S.; W. Kitchen Parker, F.R.S.; F. H. Wenham, C.E. Treasurer—J. Ware Stephenson, F.R.A.S. Secretaries—H. J. Slack, F.G.S.; C. Stewart F.L.S. Council—J. Bell, F.C.S.; F. Crisp, B.A.; Dr. W. J. Gray; J. E. Ingpen; S. J. McIntire, H. Lee, F.L.S.; W. T. Loy; Dr. H. Lawson; H. Perigal, F.R.A.S.; A. Sanders; C. Tyler, F.L.S.; T. C. White. Assistant Secretary—Walter W. Reeves.

Royal Horticultural Society, Jan. 21.—Scientific Committee.—A. Smee, F.R.S., in the chair.—The Rev. M. J. Berkeley sent portions of holly stems pierced by the larva of the wood leopard moth (*Zeuzera Æsculi*).—Prof. Thiselton Dyer exhibited a small branch of *Vitis gongylodes* from the Victoria House at Kew. The end appeared to have been broken off, and the adjacent internodes had (apparently in consequence) swollen into a mass like a small cucurbitaceous fruit.—Prof. Lawson remarked that an Indian vine (*Vitis quadrangularis*) ordinarily had the internodes swollen, though not to anything like the same extent.—A conversation then arose as to the production of aërial roots by vines.—Mr. Worthington Smith, F.L.S., detailed the results of a series of experiments made with the object of ascertaining how far perfectly sound potatoes can be contaminated by contact with infected ones.—Mr. Andrew Murray, F.L.S., made some remarks on interesting plants suitable for horticulture which he had met with in the Rocky Mountains.

General Meeting.—Mr. W. A. Lindsay, secretary, in the chair.—Prof. Thiselton Dyer made some remarks on a parasitic fungus, which was proving exceedingly destructive to hollyhocks. It has been identified by Berkeley in this country, and subsequently by Durieu de Maisonneuve, in France as *Puccinia Malvacearum* of Montagne; it was first described from specimens collected in Chili by Bertero.

EDINBURGH

Geological Society, Dec. 18, 1873.—On some points in the connection between Metamorphism and Volcanic action, by Prof. Geikie, president. After adverting to his previously published views regarding the connection between the protrusion of granite and ordinary volcanic rocks, the author proceeded to point out that the facts were probably capable of a wider interpretation. The metamorphism of large areas was well known to be intimately related to the contortion and plication of rocks, highly metamorphosed regions being those where the rocks had undergone the most intense pressure and crumpling. Heat would necessarily be evolved in the process of compression, and might have been in some parts sufficient actually to fuse the rocks. Such fused portions were probably recognisable in the masses of granite, syenite, porphyry, and other so-called igneous rocks so common in metamorphosed regions. These views were shared by many able geologists of the present day. The author, referring to the recent memoir of Mr. Mallet, pointed out that such conditions as those indicated by the facts of metamorphism were eminently suggestive of the probability that volcanic action had accompanied metamorphism. The extensive crumpling of the rocks of a region indicates a weak part of the crust of the earth through which the internal heat would for a time be more easily transmitted to the surface, while the effect of that crumpling would be greatly to increase the store of heat out of which volcanic energy arises. Hence both by the access given along the line of weakness to the internal heated mass of the earth, and by the increased temperature due to the contortion, water finding its way downward from the surface would encounter conditions eminently favourable for the production of volcanoes. If this speculation has any ground of truth, we should expect to find some evidence of the association of volcanic masses with wide tracts of metamorphism. Without travelling beyond our own country, we seem to have corroboration of it all along the flanks of the highly-contorted, and, over the Highlands, intensely-metamorphosed Silurian hills. The author then gave some details as to the probable thickness of rock under which the present metamorphosed rocks of the Highlands lay at the

time of their metamorphism, and showed that it was probably comparatively small. They were in great measure, if not entirely, metamorphosed before the time of the Lower Old Red sandstone. But the process of metamorphism was no doubt a very prolonged one, and we should therefore be prepared to find proofs of its progress at widely separated periods. It is now well known that low down in the Old Red sandstone of the Midland Valley of Scotland enormous sheets of felspathic lavas and tuffs occur, forming such chains of hills as the Saidlaws, Ochils, and Pentlands. No earlier traces of volcanic action have yet been met with in Scotland, but these masses prove that when that action began it was developed upon an enormous scale. The author believed the inference might with much probability be drawn that this vast effusion of volcanic material was a consequence, or it might even be to some extent an accompaniment, of the crumpling and metamorphism of the older Silurian rocks. He drew attention to the way in which these volcanic rocks bordered the Silurian areas on both sides of the broad lowland valley, and to the numerous remarkable bosses of granite, syenite, and porphyry by which the Silurian tracts were pierced. That many of these bosses were formed by the actual fusion of the stratified rocks themselves seemed to him highly probable. But he held also that some of them marked the lower parts of the actual orifices out of which the volcanic materials of the Old Red sandstone had issued. He alluded especially to the singular rounded or dome-shaped hills of granite, felstone, and quartz-porphyry by which the Silurian uplands of the southern counties are dotted, and which, from their general form and their relations to the surrounding stratified rocks recall some of the characters of true volcanic "necks." The sheets of lava and tuff have been preserved in the broad lowland valley owing to faulting and subsidence, while they have been removed from the surrounding hills by denudation, so as to uncover the roots of the pipes or funnels from which they were emitted. After the enormous masses of volcanic materials erupted during the period of the Lower Old Red sandstone, the underground forces gradually declined in vigour, and as the author had shown, became reduced in Permian times to the production of a few small cones scattered over the midland valley, and down the valley of the Nith. The remainder of the paper was devoted to the Tertiary volcanic rocks of the western Highlands. The author showed that in Skye, Raasay, and Mull, masses of granite and quartz-porphyry were associated with the volcanic rocks in such a way as to suggest a community of origin. Even at a distance from the main mass of the basalt plateaux, granite occurred which was almost certainly of Tertiary date. The picturesque granite of Arran, for example, which had long been known to be at least post-carboniferous, he now firmly believed to be of the same age as the terraced hills of Skye and Mull, that is, younger in date than the soft clays on which London is built, and it appeared to be associated with actual *coulées* which had, in some cases, suffered an enormous denudation like that of the Scur of Eigg. He had not yet been able to show that the renewed and prodigious outburst of volcanic action in Tertiary times had been associated with the metamorphism of any wide region, and perhaps no data are obtainable to throw light upon this question. But the extravasation of granite rocks at several places seemed to indicate that metamorphism had taken place, and at least showed, as Mr. Jukes long ago pointed out, that molten granite might be associated with true volcanic action, though it did not reach the surface as granite.—On fossil cones from the Airdrie black-band ironstone, by G. A. Panton.—Notes on the geology of India, by Andrew Taylor.

MANCHESTER

Literary and Philosophical Society, Jan. 27.—R. Angus Smith, F.R.S., vice-president, in the chair.—"On a Source of Error in Mercurial Thermometers," by Thomas M. Morgan, Student in the Laboratory of Owens College. While engaged in distillation, the thermometer, which was placed in a Wurtz tube so that the column of mercury was entirely surrounded by the vapour of the distilling liquid, was found after some days to indicate three degrees too little—a discrepancy caused by volatilisation from the surface of the column of mercury and condensation on the upper part of the tube. By causing the mercury to flow to the end of the tube and back, the condensed portion was gathered up and the correct temperature indicated. It has since been observed that after each day of distillation, with liquids boiling between 60° and 100° C., a quantity of mercury equal to 1° or 1°·5 volatilises.—"Notes on fossil Lithothamnia (so-called Nulliporæ)," by Arthur Wm. Waters, F.G.S. These attain their greatest development in the Leithakalk, a miocene formation which is principally, in some cases almost entirely, composed of these algæ. But they are in no way confined to the Leithakalk, being also very abundant in the eocene, especially the upper division; the so-called granit-marmor, or Bavarian marble, a nummulitic formation, is very largely composed of this concretionary-looking body. In North Italy it abounds in the eocene formations which are so largely developed in the Veronese and Vicentin. In many places the formation is some hundred feet, much more than half composed of the Lithothamnium. It occurs abundantly in Hungary and Switzerland. The so-called pisolithic limestone of Paris is according to Gümbel about eight-tenths stone algæ; also M. Mario, Astrup; the pleiocene of Castel Arquato; and in fact it seems to be found in most of the tertiaries on the Continent; it is further found in the chalk at Maestricht, and in the jurassic sponge beds at Schwabenbergs. The object of this paper is to draw attention to the great masses of these bodies and the importance of always noticing their occurrence in geological formations, since it should be a very material help in regard to the climate, and the conditions of the coasts and currents, besides being of great stratigraphical assistance; nor is it of less importance to note carefully the growth of recent ones, for only through a knowledge of the present can we interpret the past.

PARIS

Academy of Sciences, Jan. 26.—M. Bertrand in the chair.—The following papers were read:—Note on magnetism, in answer to M. Gaugain, by M. J. Jamin.—Direct demonstration of the equation $\int \frac{dQ}{T} = 0$ by M. A. Ledieu. This was a continuation of the paper read at the last session of the Academy by the same author.—Note on the Rhone irrigation canal, by M. A. Dumont.—Several papers on the action of water on lead, were received.—Organogenesis compared with androgenesis (*l'androcée*), by M. Ad. Chatin. This part of the paper dealt with the *Saxifrages* and *Crassulaceæ*.—On the lateral solfataras of the Chili volcanoes, and on certain new minerals, by M. L. Domeyko.—On the history of the question as to the passage of birds through the air, by M. A. Penaud.—On the shocks of earthquake at Nice, by M. Prost.—Determination of the pluckerian numbers of envelopes, by M. H. G. Zeuthen.—On the apparent orbit and period of revolution of the double star ζ Herculis, by M. Flammarion.—On the variable state of voltaic currents, by M. P. Blazerna. This was an answer to M. Cazin's recent remarks on the subject.—On a new saccharometer and a new method of obtaining an absolutely monochromatic sodium flame, by M. Laurent. The latter object is attained by interposing a cleavage plate of a crystal of potassic dichromate between the polariser and the flame. This absorbs nearly everything but the yellow light of the flame.—Researches on the flow of liquids through capillary tubes, by M. A. Guerout.—On a new laboratory balance, by M. Deleuil.—On ethylic oxalurate and oxamethane cyanurate, by M. E. Grimaux.—On the grafting of dental follicles and of their constituent organs, separately by M. Legros and Magitot.—Remarks on M. Martin's paper on the comparison of the anterior member of the "*Montotremès*," with those of birds and reptiles, by M. E. Alix.—Note on the ammoniacal fermentation of urine, by M. A. Lailler.—On the pretended emission of ozone by plants, by M. J. Bellucci. The author had made a number of comparative experiments on this subject. He found the colouration of the test paper to be due to the combined action of light and moisture.

PHYSIOLOGY AT CAMBRIDGE

WE are not of those who believe that the *quality* of the scientific work produced by any country as a whole, is dependent to any great extent on the facilities afforded for special study, though the *amount* yielded in any special direction varies directly as the opportunities and encouragement which are offered. All experience goes to show that the ability of the individual is a constant quantity, and that whatever direction his mind takes, as the result of the circumstances in which he is situated, he is sure to rise to a certain standard of excellence in the quality of his productions, and no higher; in other words, the same facts put before two men of different mental powers will be employed in producing results of different quality, dependent on those powers. The backward state of physiology, and it may be said, of biology generally in comparison with the more exact sciences, has recently become so conspicuous, that attempts are being made by many of the leading scientific men to attract into these comparatively untrodden paths some of those able minds which would otherwise have devoted their best energies to the mastery and further elucidation of points in a subject such as mathematics, which may be almost said to have reached the limit of human mental power, as far as the methods at present at its disposal are concerned. In biology and physiology, however, the case is very different; their students may be said to be suffering from a glut of facts and disconnected minor theories, which want the assistance of some master minds to weed and connect them, so that the road may be made more easy for other less gifted workers. That such is the case is rendered evident by the undecided and tentative way in which most biological problems are on all sides discussed. Opinions the most opposite are held on fundamental points by partisans of different schools, and discussion becomes more a question of which side can be most subtle in its language or most dogmatic in its statements, rather than which is the true exponent of the subject under consideration. In such cases the precise statement of the problem by a master-mind would set the question at rest once and for all.

There are, however, many difficulties in the way of getting men suitable for this higher work, and for more than one reason. One of these is that there are very few who can be made to undertake the thorough training in more than a single subject, that is necessary for it. A student of ability at the University of Cambridge, for instance, takes up mathematics, and too soon finds that he has every reason to expect considerable pecuniary reward if he devotes the whole of his period of studentship to working for his tripos; he cannot but devote the whole of his time to the single subject, for otherwise those of equal powers who did so would beat him in the race and prevent his appearing in the tripos list in that position which insures him a fellowship, and therefore a competency. He keeps to his subject and reaps the reward; but by that time other duties, generally of a social nature, together with the narrowing effect of his one-sided education, have removed all his inclination to strike out a fresh line of thought, and he commences the routine of life, acquiring by every-day experience those facts which so many others of equal ability have learned before, and which he cannot therefore turn to any good account. The great defect of the Cambridge mathematical tripos is that it is too ultimate, and too complete in itself. The day on which the list comes out is that on which most think that mathematics has done as much good to them as it can do, and on that day most throw over for ever that genuine method of working which has occupied so much of their time and thought during the three or more previous years, never to return to it.

Things being so, all must have felt intense satisfaction at the establishment at last of laboratories in Cambridge, such as that for Practical Physiology by Trinity College, under the able superintendence of Dr. Michael Foster, and that for Practical Physics by the Chancellor, under Prof. Clerk-Maxwell, whose return to Cambridge has itself been a great stimulus to the advance of the subject in which he so greatly and so justly shines.

The first instalment of original papers from the former of these newly-founded institutions has recently been published. From the manner in which the researches have been conducted, from the thoroughly scientific and careful method of work adopted, the great discretion and experience of the Professors, as well as the excellent quality of the minds, with the assistance of which he has to deal, are evident. No teacher can help having a feeling of satisfaction at such work as that of Mr. Balfour and Mr. Liversidge, which shows signs of excellent mental training as well as a thorough love of the subject. Dr. Foster's standard is evidently a high one, and from the papers before us it is certain that on future occasions only thorough work, based on well-verified facts, arrived at by the most approved modern methods, and checked by the researches of previous authors, are to be expected from his laboratory.

Besides the papers on the development of the blastoderm and blood-vessels of the chick, and on the amyloid ferment of the pancreas, by the two above-mentioned authors, Dr. Martin gives some short notes on the structure of the olfactory mucous membrane in connection with the observations of Max Schultze and Exner. Mr. Dew-Smith records the results of observations—made with the assistance of that beautiful instrument the pendulum myographion—on double nerve stimulation, or the simultaneous stimulation, by two pairs of electrodes, of a single nerve, with well-marked and very instructive results. Mr. Yule also has a paper on the mechanism of opening and closing the Eustachian tube, in which, besides clearing up some points connected with their physiological function, he throws fresh light on the correct anatomy of their pharyngeal orifices.

In one of the papers, that by Dr. Foster himself, which is referred to by Mr. Lewes in this Journal (NATURE, vol. ix. p. 83), Mr. T. O. Harding, senior wrangler in 1872, is mentioned as one of those who have been working in the laboratory. This is a most promising sign; for, as previously remarked, nothing is more wanted than the assistance of such men, in order to show the bearing and value of the various facts laid stress on by pure physiologists. We hope that

Dr. Foster will be successful in attracting other advanced mathematicians to the study of his subject; and better still, that he will be able to persuade those who are in the beginning of their undergraduate mathematical education to devote some of their spare time—quite a recreation as it would be—to learning the first principles and the methods of physiological research, under his able supervision.

Truly Dr. Foster and Dr. Clerk-Maxwell have a noble work before them, and we may hope that by their example and precept Cambridge may after a lapse of thirty or forty years, in the matter of physical and physiological research, be on a level with a second-rate German University.

ATHENIAN TEXT-BOOKS OF SCIENCE

Εγχειριδιον της Χημειας, κατα τας νεωτατας της επιστημης προοδους. (Υπα Αναστ. Κ Χρηστομαναυ. Εν Αθηναις. 1871.)

Επιστημονικα Παραδοξα. (Υπο Δ. Σ. Στρουμπος. . . . Αθηνησι, 1864.)

Περι Αερος και των Ενεργειων Αυτου. (Υπο Δ. Σ. Στρουμπος, 1869.)

Περι των Γνωσεων και των Δοξασιων των τε ἀρχαιων και των νεωτερων ὡς προς τα φυσικα φαινομενα εν γενει, και των μεθοδων τον ερευναν αυτα. (Υπο Δ. Σ. Στρουμπος, 1858.)

THE University of Athens has existed for no more than thirty-seven years. Two of its four Faculties, —the Faculty of Medicine and the Faculty of Philosophy, require a knowledge of natural philosophy and chemistry. It is difficult to understand how these subjects could have been taught at first, for the students by no means often understand French, and no Greek books on science then existed. No doubt the professors taught as Plato and Aristotle taught; and the note-book of the student had to be his text-book. But matters have changed since then: the demand for text-books in Greek has caused them to appear; slowly indeed, for we have seen but few books on science, but we may hope that the original text-books which are now beginning to appear are the first of a continuous series. Do not let it be imagined that the works whose titles are given above are the only works on science we could find in all Athens. There is a big book on Physics by M. Damaskenos, who has also written on trigonometry and meteorology; there are various memoirs by M. Stroumpos on the refraction of light; on the internal constitution of flame; on the fundamental principles of hydrostatics, &c. The University is tolerably well supplied with physical and chemical apparatus, and in good time, we hope, some good student-work will be done there.

Many of the professors have studied in Paris, and we see evidence in the text-books of French science and of French thought. Prof. Chrestomanos appears, however, in the compilation of his Chemistry, to have consulted most of the recent books and memoirs. We are glad to see Canizzaro often quoted as an authority. The work does not present any specially noteworthy features, but it is sound and eminently clear. The phraseology is at times somewhat strange to a western student; thus we do not employ such words as "Physiography" and "Phutology." . . . After some prefatory remarks concerning the division of the sciences, we have a few pages given to the history of chemistry. The period of Alchemy is wrongly stated to extend from 400 to 1500 A.D. Then Iatrochemistry from 1500 to 1650; Phlogistic chemistry from 1650 to 1783; the new chemistry of Lavoisier and Davy, and so on to the chemistry of Kekulé and Canizzaro. This is followed by a short account of physical chemistry; then an account of crystallography with good figures of crystals. Although many of the names of our elements are derived from the Greek, the table of elements looks rather puzzling: lead is of course *μόλυβδος*, while molybdenum becomes *μολυβδαίνιον*; platinum is *λευκοχρυσος*; tungsten (or Wolfram) is *βολφραμιον*; nitrogen is at the beginning of the alphabetical list; copper near the end. Again, as to compounds the names of the oxides of nitrogen read as *ὑποξείδιον ᾽Αζώτου*; *ὀξείδιον ᾽Αζωτου*; *νιτρῶδες ὀξὺ*; *ὑπονιτρικὸν οξὺ*; *νιτρικον ὀξύ*. The theory of atomicities is well developed: niobium and tantalum are the only pentatomic elements; while molybdenum and tungsten are the only hexads. The peculiar atomicities of nitrogen and iron are not noticed. The building up of compounds on the type respectively of one, two, and three molecules of water is fully discussed (*μόριον* is the term used in place of our low-Latin *molecula*). Full tables of grouped elements appear; and the naming of compounds is considered. After this considerable and important introduction the work begins with hydrogen in the usual manner, and the account of the other element follows in due course.

The "Scientific Paradoxes" of Prof. Stroumpos is a volume of essays on physics and physiology; including magnetism, electricity, illusions, alchemy. Here too we find paradoxes of another kind; would Mr. Glaisher recognise his name as *ὁ Γλαισχερος*, or Mr. Coxwell as *ὁ Κοξουέλλος*? The treatise on the Air, by the same author, is a tolerably complete treatise on pneumatics, illustrated by very crude, but original and sufficient woodcuts. The discourse on the history of Science is very interesting, and full of excerpts from Plato, Aristotle, and other ancient writers. For them we think Prof. Stroumpos has claimed too much; we cannot with any degree of certainty assert that Aristotle discovered that the air possesses weight. His experiment at the outset is altogether faulty, for he tells us that an inflated skin (*ὁ πεφυσημένος ἀσκὸς*) weighs more when filled with air than when empty, that is, not inflated. This of course we know from the law of Archimedes is false; a bladder full of air weighed in air can weigh no more than the uninflated bladder.

These works constitute the commencement of Athenian science. The city, while its art, and literature, and philosophy, have unhappily long passed their culminating point, is more scientific than it has ever been before. Not far from the place in which the Peripatetic made his experiment with a crude statera and an empty wine skin with Theophrastus as demonstrator, Stroumpos now weighs his really vacuous vessel, and Chrestomanos explodes oxygen and hydrogen. Thirty years of science in a remote city, out of the highways of European intelligence, cannot effect much; but we hope in the course of the century original workers will multiply in Athens, and as much will be done to promote chemistry and physics,

as has been done by Dr. Schmidt in the service of astronomy on the Hill of the Nymphs, over against the Acropolis.

G. F. RODWELL

THE ACRIDIDÆ OF NORTH AMERICA

Synopsis of the Acrididæ of North America. By Cyrus Thomas, Ph.D. Published in Vol. v. of Report of the United States Geological Survey of the Territories. Pp. 1-262. (Washington, 1873.)

IN a prefatory note to this volume the United States Geologist, F. V. Hayden, tells us that Prof. Thomas's work on the Acrididæ of North America is published "in the belief that it is a substantial contribution to natural history;" and certainly it is impossible, on a perusal of the work, not to share in this belief; it is, moreover, another proof of the great boon conferred upon natural science by public surveys and Government expeditions. Serious and extended works on natural history (except, perhaps, those relating to some few very popular branches of it) would seldom be produced, or in many cases their materials be collected, if it were not for the assistance of natural history societies, public surveys, and expeditions; organisations of these kinds can afford to disregard the commercial aspect of the question, and are able to bestow upon the public, works which private enterprise would seldom venture upon. Among insects, the Orthoptera (of which order the Acrididæ are a well-defined family group) are certainly not the most popular among entomologists, though, for many reasons, of great interest to others. Few persons but have some cherished association with, for instance, the persistent chirp of the cricket on the hearth, or the shrill stridulations of some of the grasshoppers; there are, again, few more wonderful sights in the insect world than a flight of locusts; and few natural scourges are more terrible than those inflicted by the devastations of these rapacious creatures; the walking-leaf and stick insects (Mantidæ and Phasmidæ) are also very popular objects for sightseers in natural history museums. The lack of general popularity among collectors and students arises probably in great measure from the Orthoptera being commonly less sightly as cabinet objects than some other orders of the Insecta, though perhaps it arises as much or more from the paucity of works combining both a general and special treatment of the whole, or of well-defined groups, of the order under consideration. Dr. Thomas's work is undoubtedly calculated to encourage the study of the large group included under the *Acrididæ*, and to be peculiarly acceptable to American entomologists, for it not only describes a large number of North American species (both known species as well as new ones), but it gives, in an "Introduction," pp. 9-45, a concise view of the general classification of the Orthoptera, with the relation of the Acrididæ to the other sub-ordinal groups, their structure, internal and external, and the distribution of genera and species over North America. This introductory part of the work is illustrated by two remarkably clear and good woodcuts, showing all the different portions of external structure, with the name of each part.

The remarks of Prof. Thomas, in the chapter on Classification, bring strongly before us the difficulties and imperfections involved in a linear arrangement of any portion of the animal kingdom; but if a real genealogical relationship be that which exists between all living creatures, then it is apparent at once how comparatively unimportant is (generally speaking) the mere linear arrangement of the series; it is, indeed, the only possible one on paper, but in reality some of the most important relationships do not run in one unbroken line, but in lines diverging at many different angles, and in many different planes. Dr. Thomas considers the Orthoptera as arising from the *Crustacea*, and, after reviewing the various extant arrangements of their families, divides that under consideration—ACRIDIDÆ (*i.e.* the saltatorial Orthoptera, or Grasshoppers with comparatively short antennæ), into two *sub-families*—ACRIDINÆ and TETTIGINÆ; the former of these is sub-divided into three divisions: — CONOCEPHALIDES, ORTHOCERIDES, and XIPHOCERIDES, forming (in the order in which these are here given) seven groups:—1. PROSCOPINI; 2. TRYXALINI; 3. TRIGONOPTERYGINI; 4. ŒDIPODINI; 3. ACRIDINI; 6. XIPHOCERINI; 7. PHYMATINI (?). The three first of these groups belong to the *Conocephalides*, the two next to the *Orthocerides*, and the two last to the *Xiphocerides*.

The sub-family TETTIGINÆ is undivided, and consists of a single group, TETTIGINI.

A useful and concise Synoptical Table gives the leading characters of the author's sub-families and subordinate groups; and another Synoptical Table of the United States genera (p. 49), as well as an excellent plate containing seventeen figures, will give great assistance to the student of the American species. Pp. 55—245 are wholly occupied by scientific descriptions of species, genera, and other larger groups. This portion of the work is divided into two parts, the first treating of the Acrididæ of the United States (pp. 55—190); the second (pp. 195—245) of those of North America, not found in the United States. The number of genera characterised as North American is 45; that of species 227. In the United States (exclusive of *Tettiginæ*, which contain 3 genera and 12 species) are, at present known, 125 species of 25 genera; of the former, *forty*, and of the latter, *four* are described as new; and six others also are described as not hitherto known to be represented in that more restricted locality. At pp. 3—6 will be found a boon to the American orthopterologist in the shape of a list of those authorities which contain descriptions of the genera and species of Acrididæ belonging to the North American fauna. Another exceedingly useful feature of Dr. Thomas's work is a glossary at the end explaining the technical terms (to the number of upwards of 200) used in the scientific descriptions; the utility of this glossary will, no doubt, be felt far beyond the circle of students and collectors of the Acrididæ.

OUR BOOK SHELF

Daily Bulletin of Weather Reports, Signal Service, United States Army, taken at 7.35 A.M., 4.35 P.M., *and* 11 P.M. *Washington Mean Time, with the Synopses, Probabilities, and Facts for the Month of September* 1872. (Washington, Government Printing Office, 1873.)

THIS is a quarto volume of upwards of 180 pp., containing besides 90 weather-charts—three for each day of the month of September 1872. The volume is published for

the purpose of showing the method of working of this division of the U.S. Signal Service, the "Division of Telegrams and Reports for the benefit of Commerce and Agriculture." The system appears to us to be thorough and careful, and calculated to lead to valuable scientific results in the department of meteorology. For each of the three daily times mentioned in the title, there is first a tabulated meteorological record from 72 stations in the United States and British N. America, showing the state of the barometer, thermometer, humidity, wind, clouds, rainfall, weather. This is followed by a weather-map constructed on the preceding record, on which, by clearly distinguishable marks, the state of the weather at all the stations is shown, whether clear, cloudy, snow, rain, &c., the direction and velocity of the wind, and the average elevation of the locations. Following this is a synopsis of the record, in which the general results of a comparison of the particular observations are briefly stated. This synopsis is succeeded by a statement of "probabilities," which are the deductions made from the conditions exhibited in the chart, considered in their sequence, as to the meteoric changes probably to follow within the twenty-four hours next ensuing. Then come the "facts" by which the "probabilities" may be tested, these facts being a classified statement of the state of the weather at the various stations at the next succeeding time of observation, with "general remarks" showing how far the probabilities have been realised. This is done, as we have said, three times every day of the month for which this Bulletin is published, and the value of the publication to students of meteorology is evident. "As a contribution of data, at least, to meteoric science," the introductory statement justly says, "and a demonstration that it needs only that governments should will and act through proper organisation to make meteoric knowledge of daily and practical use to the people, the publication must have its value." The Government of the United States deserves the highest credit for the wisdom it displays in perceiving what the true interests of the country are, and for its liberality in supporting a scientific department such as the one from which this Bulletin issues, whose business it is, by publishing the result of scientific research, to "benefit commerce and agriculture." By a patient pursuit of the system exhibited in this Bulletin, and by adopting what improvements may from time to time suggest themselves, we have no doubt that results of great value to science will follow.

The Treasury of Botany: a Popular Dictionary of the Vegetable Kingdom, with which is incorporated a Glossary of Botanical Terms. Edited by J. Lindley, M.D., and Thos. Moore; assisted by numerous contributors. New and revised edition, with Supplement. (London: Longmans, Green, and Co., 1874.)

THERE is no more difficult task than that of editing re-issues of scientific works published some years since. The progress of science is so rapid, the number of new facts accumulated year by year so enormous, that the most satisfactory and exhaustive treatise on any subject written by a specialist in that subject, becomes to a certain extent obsolete or imperfect in ten years. And yet, where can our scientific men be found with leisure to write or edit new dictionaries of science every ten years? The re-editing of old dictionaries seems, therefore, the inevitable alternative, though one attended with many disadvantages, which disadvantages are greatly increased when the objectionable plan has been adopted, as in the present case, of stereotyping the plates of the original work. The new facts can then only be placed before the reader in the form of a supplement, which may often seem at variance with the work itself, while errors or imperfect descriptions cannot fail to be reproduced. Lindley and Moore's "Treasury of Botany" was so admirable a work in its day, containing such an enormous mass of information, that a new edition must necessarily be welcome, although botanical science has made such rapid strides since its first publication in 1866; and the welcome will be more hearty when it is found that the new matter has been entrusted to such competent authorities as Dr. Masters, Prof. Thiselton-Dyer, Mr. Britten of the British Museum, Mr. Jackson of the Kew Museum, and the surviving editor. The only fault we have to find with the supplement is that it occupies five times too little space; under 100 pages out of 1,350 is clearly entirely insufficient for even a brief account of the main additions to botanical knowledge made during the last eight years. Had the new contributors been allowed a larger space, the book would have been a far more satisfactory one. It is to be regretted that at a time when so much attention is being paid to vegetable histology, a description of the vegetable cell should be republished without comment, not only so inadequate, but so misleading in our present state of knowledge, as the following:—"Cavities in the interior of a plant; the cells of tissue are those which form the interior of the elementary vesicles;" or that no description whatever should be given of the structure or mode of formation of starch-grains. As a dictionary of botanical nomenclature and classification the work is most ample; and on this ground only the "Treasury of Botany" is one which no botanical student can afford to be without.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Simultaneous Meteorological Observations

IT is doubtless familiar to most of your readers that at the Meteorological Congress at Vienna a proposal was adopted which was made by the War Department of the United States regarding the institution of a system of simultaneous daily observations all over the globe.

I have recently received the subjoined letter from the chief signal officer at Washington on the subject.

It may be of interest to your readers to know that invitations have been issued by this Office to a large number of observing meteorologists in the United Kingdom, on whose co-operation I considered I might count, and that I have received returns from sixty-one stations for the first fortnight of the year, and from sixty-four for the second, so that we may consider that the plan has met with general acceptance with the public.

I am ready to receive the names of any gentlemen who are willing to assist in the scheme, and who possess properly verified instruments, and shall be very happy to answer inquiries on the subject. ROBERT H. SCOTT, Director

Meteorological Office, London, Feb. 17

"War Department, Washington, D.C.,
"Jan. 20, 1874

"Sir,—At the recent Meteorological Congress at Vienna a proposition was adopted to the effect that it is desirable that, with a view to their exchange, at least one uniform observation of such character as to be suitable for the preparation of synoptic charts be taken and recorded daily and simultaneously at as many stations as practicable throughout the world.

"The United States has an especial interest in reports and exchanges of this character, for the uses of the particular work in which it is engaged. It is hoped that when they are sufficiently extended, satisfactory solutions of many questions from time to time presenting themselves to this Office, and which now cannot be answered, will be arrived at.

"I have the honour, therefore, to request the establishment of a regular exchange between the Meteorological Office of which you are Director, and the Office of the Chief Signal Officer at

Washington, of uniform reports made from simultaneous observations taken daily at as many of the stations under your charge as it may be practicable for you to instruct or request to furnish such reports, or from other stations from which they may be voluntarily tendered, and of similar reports to be taken at the established stations of this Office throughout the United States. The reports to embrace, at least, pressure (reduced), temperature, wind, rain, relative humidity, and clouds, and to be made at 12.43 P.M., Greenwich mean time. The records to be printed or in manuscript, as you prefer, and to be mailed (as many of them as may be ready for exchange on the dates) in packages, on the 15th and last days of each month. Should circumstances render it inconvenient for your Office to furnish such reports without blanks for days on which they will necessarily fail to be taken, the records will be none the less gratefully received. Self-registered records will be very acceptable. In return exchange it is proposed to mail to your Office on the 15th and last days of each month the record of the simultaneous report prepared for that purpose in the form of which the enclosure herewith is a specimen for a single day.

"The data so to be exchanged are intended for any use either Office may wish to make of them.

"As an acknowledgment to those who may, upon your invitation, assist in a work so much wished for on the part of this Office, it is proposed to send to you monthly copies of the 'Official Monthly Weather Review,' with its Maps, for distribution to each of those so assisting, or other papers published by this Office, if so requested.

"In requesting this exchange as a part of a system to which it is hoped a very wide extension can be given, the Chief Signal Officer recurs with pleasure to the prompt encouragement received at your hands at the earlier steps for its adoption, and is gratified to announce that co-operation for similar exchanges of records, commencing on January 1, 1874, has been requested or is in progress with Prof. H. Wild, Director, Imperial Observatory, St. Petersburg; Prof. A. Coumbary, Director, Imperial Observatory, Constantinople, Turkey; Prof. Carl Jelinek, Director, Imperial Observatory, Vienna, Austria; Prof. Quetelet, Director, Meteorological Observatory, Brussels, Belgium; Prof. Buys Ballot, Director, Meteorological Institute of the Netherlands, Utrecht, Holland; and Prof. H. Mohn, Director, Meteorological Institute of Norway, Christiania, Norway. As time and its faculties will permit, this Office will seek additional aid. The advantages to accrue to the service in the United States are certain, and the hope is not unfounded that as the co-operation sought will be world-wide, so also will be the benefits resulting.—I am, &c.,

"ALBERT J. MYER
"R. H. Scott, Esq." "Brigadier-General, U.S.A.

Remuneration of the Contributors to Milne-Edwards' "Mission Scientifique au Mexique"

EN vous remerciant de l'envoi d'un article (vol. ix. p. 260) relatif aux singulières assertions contenus dans une note de M. Gray, je vous demanderai la permission d'ajouter que ni M. Duméril ni aucun des autres naturalistes qui prennent une part, soit directe, soit indirecte à la publication de l'ouvrage sur la Zoologie du Mexique ne recoivent pour ce travail une rémuneration pécuniaire quelconque. C'est gratuitement et dans l'intérêt de la Science seulement qu'ils s'en occupent; par consequent les renseignements fournis à mon estimable ami M. Gray, par je ne sais qui, sont faux.

Recevez, Monsieur, l'assurance de ma consideration tres distingué.

MILNE-EDWARDS

Animal Locomotion

IT is not my intention to go through the detailed proofs of the different statements in my review of his work to which Dr. Pettigrew objects, and which his letter of last week in no way falsifies, nor to show how he has quite missed the point of an observation of mine which he condemns as "utter nonsense," but simply to answer the question with which he ends his remarks. At first sight it might seem that the active dilatation of the heart during diastole did depend on an inherent power in the muscular fibres of the ventricles to elongate, but the peculiarities of the coronary circulation are quite sufficient to explain the phenomenon without the introduction of so unnecessary a theory as that of Dr. Pettigrew. For in the heart when removed from the body, as in the living body during diastole, the injection of fluid into the coronary vessels causes the whole heart to open up from the congestion of the ventricular walls, and so produce the active dilatation which is well known to occur. This explanation was proposed by Brücke, and by myself some years later (Journal of Anat. and Phys.)

A. H. GARROD

WHILE admitting that Dr. Pettigrew appears to have made mistakes in his figures, and that he has not explained his views in the clearest manner, nevertheless it appears to me that, on the very important question of whether a bird's wing during onward flight moves downward and forward or downward and backward, he is right in asserting the former to be the fact.

The arguments of Mr. Garrod and Mr. Ward against this view seem to be founded on two assumptions—that the wing during its down-stroke is an inflexible plane, and that during its upward motion the quills open so perfectly that there is neither vertical nor horizontal resistance. But every feather of a wing is highly flexible towards its extremity, so that during the down-stroke the whole posterior margin of the wing must be curved up by the pressure of the air, thus forming a highly effective propelling surface owing to the rapid motion of this part of the wing. During the upward stroke the feathers open freely so as greatly to diminish, though not wholly to prevent, downward reaction; but the broad soft web of each quill will be bent down by the rapid escape of air between the quills, and this will necessarily give a forward motion, probably equal to that attained during the down-stroke, in which the small curved surface has a greater resistance and more rapid motion. If then the up- and the down-stroke both produce onward motion, the resultant of this motion will be in the direction of the mean position of the wings, which we may take to be about that of the body of the bird; but if the down-stroke were directed *backward* and the up-stroke *forward*, the resultant onward motion would be obliquely downward, and this downward angle of motion would tend to be so much increased by the continual gravitation of the body that the surplus vertical reaction of the down-stroke over the up-stroke would not be able to overcome it. A slight upward angle of the mean position of the wing-plane seems therefore to be essential to secure horizontal forward motion as a general resultant of the upward and downward action of the wings under the influence of gravitation; and to Dr. Pettigrew belongs the merit of showing that this is one of the most important characteristics of the flight of birds, and, probably in a still greater degree, of that of insects. A bird's wing is a highly complex apparatus, subject to a variety of flexures and motions in every feather; and it is only by a careful consideration of the action of the resisting medium on these variously curved elastic surfaces, both during the upward and downward motion of the wings, that we can arrive at any definite notion of their supporting and propelling effect. The experiments of Prof. Marey do not seem to contradict the theory of Dr. Pettigrew, as far as I can make out from an abstract of these given in the "Ibis" for 1870, p. 267; though, as his apparatus only gave the motion of the wing relatively to the body of the bird, they are not of very much value in determining the absolute angular position of the wings, which is what we want to arrive at. The highly-inclined position of a hovering bird is more to the point, as any less degree of inclination would lead to onward motion.

ALFRED R. WALLACE

On the Variability of the Node in Organ-pipes

THE variability of the node is an unrecognised phrase. Something similar in kind relating to the node will be remembered as having been mentioned by scientific writers in a cursory manner, then set aside as evidence of too doubtful interpretation to call for more extended comment.

From the time of Savart it has been known that the nodal division of the open organ-pipe does not take place at the exact half of the length, that the half nearest the embouchure is the shorter of these "unequal halves"—a contradictory term apologised for yet sanctioned, I believe, by the late Prof. Donkin.

The displacement of the node is perhaps the most significant fact that in the natural history of organ-pipes presents itself to

the attention of the investigator, be he student or teacher. Why it should have been passed by as though its meaning were not worth wrestling for is incomprehensible. Since Savart wrote no light has been thrown on this singular phenomenon, for the explanation which has been afforded (presently to be quoted), cannot be called in any degree satisfactory. In the illustrations of nodal division given in various scientific works there is a puzzling contrariety hardly to be accounted for except on the supposition that our engravers are as niggardly conservative in design as the buried Egyptians, or that the engravings themselves are the cherished heirlooms of our publishers. In one work a representation of the manometrical nodal division after Kœnig will be given, but *carefully* corrected and revised by the aid of a pair of compasses; in another a beautifully accurate copy of the original, so lopped to suit the size of the page that much mental effort and distortion of reasoning are incumbent on the reader in vain attempts to bring the engraving into harmony with the accompanying text, young eyes are mystified, it needs cold "well-worn eyes" to appreciate these fine economics of the publishing art; in another the manometrical nodal positions will be properly defined and, by some negligent inconsistency, on an opposite page an organ-pipe be depicted, admirably exact to theoretical localisation, in direct contradiction of knowledge. Faults of this kind should not be allowed to pass, they weaken faith in the teacher and are harassing to the inquirer.

Kœnig in his own illustrations represents the displacement of the node as it is indicated under experiment, for this one condition of truth to nature had been too often before him in his manometric flames to allow of his disregarding its faithful portraiture. The difference he shows to exist as to position corresponds very closely with that we arrive at by other means, by calculation of scales and by the practical teachings of experimental study of the relations and arrangements of organ-pipes. Of the cause of the displacement Kœnig offers no elucidation.

The following explanation is quoted from Prof. Airy's treatise on "Sound and Atmospheric Vibrations." In the section on open organ-pipes he says :—

"It was found by Mr. Hopkins that the node next the open mouth of the pipe was somewhat less distant from it than that given by theory, or, which amounts to the same thing, that the place where the air has always the same density as the external air is not exactly at the pipe's mouth but somewhat exterior to it."

The extent of the disparity would be but very imperfectly comprehended under this vague delineation. Other authors have attempted explanation, in substance the same as the above, to account for the disparity; the summary of the whole is, that science brings forward no better plea than the surmise of a probable place, somewhat exterior to the mouth, which the air-wave of the *lower half* of the pipe has to attain before it can be properly said to be completed in length. Truly an illogical conclusion if this line of reasoning is carried out. In common fairness the *upper half* of the pipe may claim to be credited with a reasonable amount of wave-prolongation, seeing that at the higher orifice the internal column of air pulsates the atmosphere with far greater vigour than at the mouth, and consequently that for a similar attainment of density the due addition of wave-length would only serve to increase the disparity in relation to the *half below* the node.

A displacement of some sort thus receives acknowledgment although as yet the variability of the node is unsuspected.

The actual extent of the disparity between the "unequal halves" can be ascertained. It is subject to laws of relation of as definite a character as are found in other dynamical problems when the elements of calculation are delicately defined. An approximate estimate will be sufficient for the present purpose. For avoidance of the inconvenient "unequal halves" it will be permitted me to coin two simple terms as more distinctively representative, and to speak of them as super-nodal and sub-nodal.

If a standard open diapason pipe be made for some designed pitch, whatever that pitch may be, it may safely be predicted that the pipe will stand considerably short of the full theoretical length; æsthetically judged for musical quality, it ought to be about one-eighth less, a difference much affecting the veracity of scientific argument.

Doubtless it would be somewhat a novelty for a scientific lecturer to tell his audience that one-eighth of the whole wave-length was lost by conversion into organ-pipe vibrations, yet, unless he innocently accepts the ironical reply of Galileo on the pump question, that "perhaps Nature is indifferent to a few feet," he is strictly in this dilemma: if the pipe is a natural standard of wave-length, the velocity of sound in air computed on the basis of the pipe's length falls very far short indeed of the philosophical estimate, 1,125 feet per second; on this ruling the latter should be pronounced to be irreconcileably wrong, *or else* the frank admission made that there is no "necessity of relation" that the wave-length in an organ-pipe, giving a defined pitch, and the wave-length in the free air corresponding to that note should be identical.

Taking the several classes of pipes, from the Diapason to the Vox Angelica, ranging from the pipes of the most vigorous to those of the softest intonation, the amount of difference from full measure varies from one-eighth to one-twelfth *less* than that which theory demands. The loss is mainly due to the cause which enforces nodal displacement.

Our immediate inquiry is, what is the extent of displacement of the node, and what its variability? Divide the length of the already reduced pipe into seven equal parts, and the unequal halves will be in the ratio of 4 to 3 Four parts belonging to the super-nodal half, and three parts to the sub-nodal half, subject to a relative variability, according to the position of the pipe in the range of octaves, and subject to a fluctuating variability determined by force of wind, diameter of pipe, character of scale, relative size of mouth, mode of voicing, and other details, changing the proportion, perhaps, to 6 : 5, or even to 7 : 6. Whatever the extent of the variability, change in result rigidly follows change in details, with a calculable value. When, instead of the fundamental note, the pipe vibrates in harmonic nodal divisions, the lowest half-segment takes upon itself almost the whole difference, and not merely a proportional share in comparison with its segmental relation to the whole pipe. A remarkable fact, but one fully accounted for in that which I have termed the aëro-plastic reed theory (NATURE, vol. viii. p. 25) for it is easy to me visibly to demonstrate that the harmonic-independent and the harmonic-concomitant are originated in the pipe by totally different natural processes.

The nodal difference detected by Mr. W. Hopkins was much smaller in extent, but there is an important distinction not to be overlooked: his experiments (recorded in the Transactions of the Cambridge Philosophical Society, vol. 5) were not made with organ-pipes, but with glass tubes supported in position over a glass plate, the plate being set in vibration by friction. He expressly rejected organ-pipes by reason of their intractibility and of the difficulty of obtaining results from them of the nature desired.

In like manner we continually find experimentalists rejecting organ-pipes as insubordinate pupils; they prefer dumb pipes and the artificial speech by tuning-forks, and having obtained such negative evidence, make a clean transfer of their conclusions to all argumentative reasonings and expositions of the nature and functions of the original, living, speaking organ-pipes. The Hon. M. Strutt, in his paper on the Theory of Resonance, printed in Phil. Trans. Nov. 1870, says :—

"Independently of these difficulties, the theory of pipes or other resonators made to speak by a stream of air directed against a sharp edge is not sufficiently understood to make this method of investigation satisfactory. For this reason I have entirely abandoned this method of causing the resonators to speak in my experiments, and have relied on other indications to fix the pitch."

Prof. Airy is as evidently dissatisfied with the state of theory and experiment, using such phrases as these: "the matter, however, demands more complete explanation;" "that obscure subject, the production of musical vibrations in a pipe by a simple blast of air;" "possibly when the mathematical calculus is farther advanced, this may be shown," &c. Beyond the province of mathematical analysis his survey is keen, and with foresight of the results of possible experiments.

At the present date our best authorities are in effect repeating the assertion of Biot that "the particular properties of the vibrations of confined air in tubes are not yet sufficiently explained." The disturbing influence of some unknown agency may be discerned in Dulong's experiments of filling organ-pipes with various gases, and estimating the velocity of sound in these gases by the pitch produced. Similar experiments on this method are referred to by Herschel, and he, noticing how the results gave for hydrogen gas a velocity differing by one-fourth from that which theoretically had been calculated, could only account for it by supposing an impurity in the gas used for the experiments. There is little need to resort to the supposition of

an impurity; it is quite sufficient to know that an agreement in length of organ-pipe and aërial wave-length was assumed which does not exist, and that, moreover, the mechanical nature of the organ-pipe, and its delicate apparatus so wonderfully balanced for the attainment of its ends, had escaped observation. The admirable method of experiment for ascertaining the velocity of sound in gases, devised by M. Kundt, by means of glass tubes and lycopodium seed, is free from the same source of error; and, as might be anticipated, comparison shows a marked difference in estimates. In respect of carbonic acid gas and hydrogen gas, for instance, Dulong differs from Kundt, his estimate in the one case being less by one-fifth of the whole, and the other more by one-fourth; the divergence interprets itself, indicating the relation of their densities to the compelling force, the unseen mechanical action at the mouth of the organ-pipe. This will be clear when the "air-moulded reed" is fully understood in its nature and functions. When the magnetism of the earth is perceived, the dip of the needle to the north or south of the equator in accord with its localisation is explained.

The confession of "obscurity" amounts to a concession that the old theory has been found wanting, that it is inadequate to deal with facts. Whether in dealing with the larger questions here brought into discussion, or with the simpler class, the mere modifications of structure, it is equally incapable. If, for instance, a stopped pipe is pierced through the stopper and a short open pipe inserted, say a third or fourth the diameter and a third or fourth the length, what will be the effect of this on the pitch? The old theory would reply, the added length would cause a flattening of pitch, and then will come a proviso for safety's sake, that if the change converted it into an open organ pipe then the pitch would be raised in accordance with the open length. We go to Nature for her say in the matter, and find that the pitch is raised not flattened, and that the extent is about a quarter of a tone, and that *further lengthening* of the smaller pipe takes back the pitch again just its quarter tone. If another stopped pipe is drilled at the back with a hole of a diameter a third or fourth of that of the pipe, but so that it shall be at a higher level than the lip or edge of the mouth, in effect shortening the air column by admission of external air at a higher point, what will be the result? On the old theory we should expect the pitch to be higher in consequence. Appealing to the ear we know that, on the contrary, it is flattened. These results cease to be anomalies when viewed under the new theory, and indeed they would be predicted with confidence as the necessary outcome of the conditions.

The proposition that in an organ-pipe there is no constant wave-length for an ascertained pitch, will no doubt be discountenanced as novel and revolutionary, but it is true and will have to be acknowledged. A further proposition that in an open organ-pipe there are three different velocities speeding at different rates, concurring in every vibration, and essential to the synchronic time of its note, has a still more aggressive aspect defiant of law. Not so. It is because law—"known law," does not cover the facts, is unstable in its applications, and is deficient in prevision, that there is room for new hypothesis which does not play fast and loose with nature; the utmost exactitude of length in an organ-pipe is as indispensable in this as in the older theory, but the relation is one of proportion to a system, and the least and every variation will make imperative suitable or corresponding modifications in other portions of the structure. Only a whistle, yet with more to marvel at for delicacy of organisation and beauty of adaptation "than is dreamt of in philosophy."

As regards "fixity of wave-length," that characteristic reappears in a new relation, and we shall find that, allowing for retardation by friction, the super-nodal half-wave of the pipe corresponds very closely with length in atmosphere. The cause of the displacement of the node is involved in the physical action taking place at the mouth of organ pipes, the consideration of which is reserved for a further communication.

HERMANN SMITH

Auroral Display

As a few remarks on the aurora of the 4th may be of interest to some of your meteorological readers I append the following notes:—

At 6.15 P.M. on Wednesday, the 4th inst., an aurora commenced in the northern part of the sky which gradually went down towards the south.

7.15.—Semicircle from W. to E., streamers shooting up from it.

7.25.—Light more diffused, a few streamers at N.W.

7.30.—A semicircle of diffused light from W.S.W. to E.

7.35.—Bright line of light from W S.W. to E.; no streamers.

7.40.—A very faint irregular line of light from W.S.W. to E.

7.45.—Diffused light.

7.50.—Same as at 7.45.

7.55.—Streamers shooting down from zenith all round. Very fine.

8.—Bright at N.N.E. Streamers N. and N.N.E. A sharp S.E. breeze.

8.5.—Bright light at N.W. No streamers.

8.10.—Streamers at N.E.

8.15.—Streamers at S.S.E.

9.—No aurora perceptible.

From the above, we note one peculiarity, namely, that the aurora was chiefly in W. + E. or W.S.W. and S.S.E.

WILLIAM HY. WATSON

Braystones, near Whitehaven, Feb. 9

[We have received letters concerning this aurora from several other parts of the country.]

THE PHOTOGRAPHIC SOCIETY

ALTHOUGH we published last week a letter from Mr. Baden Pritchard, Hon. Sec. of the Photographic Society, impugning the justice or accuracy of our strictures on that Society, our esteemed correspondent has not caused us to change our opinion.

We have now before us the Journal of the Society for the past year (a summer vacation of three months excepted), and certainly it furnishes *primâ facie* evidence of the most apathetic and inefficient condition which is consistent with continuous existence. The numbers contain eight pages each, the page little more than half the size of that of NATURE, and in the whole year's proceedings there are twelve pages devoted to science, half of this being a lecture by Prof. Stokes; three or four papers of considerable value on technical points of photographic interest, and much which the charity of any semi-learned society would be largely strained in giving paper and ink to.

There is no mention of scientific or other committees, no provision for them in the laws, no reports of investigations made or to be made, no notice of scientific discovery abroad or recognition of discovery at home. Mr. Pritchard has no need to assure us that the body "does not profess to be a purely scientific one"—the scientific element in it, so far as its own record shows, is purely fortuitous.

But without demanding scientific labours from a body not "purely scientific," we do not even find evidence of common activity in the research of practical problems, and if any of its members are, as Mr. Pritchard suggests, engaged in researches on the process and nature of film best suited for transit of Venus observations, they have not had faith enough in the countenance of their Society to place their labours before it, or ask its assistance in performing them.

Since our article appeared, the revolution alluded to has taken place, and that part of the Society in favour of reform having a majority at the meeting appointed for the discussion of the question, have carried an amendment to the laws providing that henceforward the Society at large shall select its council, and that the majority of the actual council shall not have the power to select for retirement such members as it sees fit and to decide who shall replace them, as has actually been the case hitherto; it has also been decided that the presidency shall rotate. These measures were, as we learn from the photographic papers, strongly opposed by the council, and upon being carried by a majority of 30 to 23 (the council itself voting in the minority) the entire body resigned.

As the meeting at which this stroke of singular policy was made, was that for the election of the new members of council, these were enabled to assume the reins of government and prevent the, otherwise in-

evitable, total dissolution of the Society. And now that the reformers have its affairs in their own hands, it is to be hoped that it will begin a new life of efficiency, and, remembering that it owes the cause of its existence to the labours of scientific men, give its most efficient aid to those scientific researches in which it has become an important element of investigation, as well as to those of a more technical nature which have given photography so great a commercial and industrial value. And on the other hand we bespeak for it the aid and countenance of all scientific men whose researches are in any way dependent on photography, and give it, in its reformation, our best wishes for that complete success and efficiency which will make it as useful to Science as honourable to itself and its members.

NOTES FROM THE "CHALLENGER"

THE following contributions to the literature of the *Challenger* Expedition appear in the *Cape Monthly.* The first contribution consists of a few notes from Commander Maclear, written on the day of the *Challenger's* departure from Simon's Bay, and will give our readers an idea of the work still before the Expedition :—

On leaving Simon's Bay, if the weather permits, dredgings and temperature soundings will be taken on the Agulhas bank; then sail made for Marion Island. This and the Crozetts will be examined ; the last may be occupied by the French as an observing station for the Transit of Venus. Then for Kerguelen Island. It is not likely that the weather will allow a regular series of soundings to be taken as hitherto, but some doubtless will be taken on the passage.

Kerguelen's, or Island of Desolation, will be a fertile field of exploration in every department of science, and as it is to be one of the stations for watching the Transit of Venus, special information will be collected for the use of the astronomers who will go there towards the close of next [this] year. The longitude of the island will be determined by chronometrical measurement from the Cape, and again to Melbourne, and with the great number of chronometers (16) that the *Challenger* has on board, the longitude should be determined very accurately.

After leaving Kerguelen, Macdonald Island will be examined, and search made for a harbour there; and then a stretch will be made to the Ice Barrier. The investigations in the neighbourhood of the ice are very important, but great care will have to be taken not to get entangled in the ice. With steam power, and the clear weather there is likely to be in February, little danger need be apprehended. If the season should be fine, some considerable time will be occupied in this region, but if not, after a short stay, sail will be made for Melbourne, which will probably be reached in the end of March. After a few days there, to obtain the rates of the chronometers, we go on to Sydney to refit and, if necessary, dock. This terminates the second stage of our voyage.

Leaving Sydney about the middle of May 1874, and carrying a line of soundings to New Zealand, we next examine the islands about the Coral Sea and Torres Straits in August 1874: New Caledonia, New Guinea, Arofura Sea, Kaepang in Timor, Java Sea, Macassar, Celebes, and reach Manilla in November. We next look up the doubtful islands of the Western Pacific ; visit New Ireland, the Solomon Islands, and Pellew, and Japan will be reached in March 1875. From Japan we cross to Vancouver's, and then to Valparaiso, examining Eastern Island and Salay group in our course. Leaving Valparaiso in the end of 1875, we go through the Straits of Magellan to Falkland Isles, Rio de Janeiro, Ascension, and England in the middle of 1876.

The other communication, of a different order, comes from a gallant Blue Jacket, who speaks for himself and the *Challengers* and their labours somewhat irreverently thus :—

FROM JACK SKYLIGHT TO HIS OLD SHIPMATE

A Letter without much Rhyme and with a little Reason

We've crossed the Line a many times in craft both great and small,
And of them 'ere fish that's thereabouts I've caught 'em nearly all.
It aint becos I wants to boast I says as "it is so,"
But 'cos I think that wot is wot I'm just the bloke to know.
I'll first acquaint you, topmate, with the nature of my dooty,
And show you what I've larned since last we met, my beauty.
I jined this craft last winter, got rated on her ledger
A swabber, jobber, scrubber, a sounder, and a druger.
I know, old ship, when this you see you'll say I'm flyin' hi,
But it's true as Polly-Arris is above us in the sky.
At sea we sounds—no matter, Bill, if every blessed thread
Aloft or low of canvas before the wind is spread,
In it comes! And down there goes, I've really quite forgotten
How many fathoms (half-inch), Bill, until we touches bottom.
Sometimes the timmey-noggie that holds the weights don't G
And then a fog* arises as is horrible to see.
We flies in all directions, like cats on houses sportin',
The luff cries out, the donkey shies, and makes a dreadful snortin'—
It aint a regular ass, Bill, but one of them inventions
They puts aboard a man-of-war with various intentions,
To wit, it nicks the complement, and gives the honest Jacks
More time to study politics and read their Sunday tracks.
The donkey does the hauling in, which is no doubt a blessin',
For if it had to come by hand, oh! lord, 'twould be distressin'.

We've a many curious ratins, a lot of long shore tallies
For scientifick genelmen, their servants, and their valleys.
Don't yer see these learned bosses have come to search the ocean,
But for what, old son, 'twixt you and I, I'm blow'd if I've a notion.
I've 'eard 'em talk of Artic drift and walleys under water,
And specs next week to find they've nab'd old Davy and his darter.
Of course you know they've got to find the link atween the species,
Some say as there's a coon aboard as liks it all to pieces;
I cannot tell, for well you know it aint the likes o' me
That's got a chance like swells abaft the curus sight to see.
The scientifick swells, old chap, are mad on mud, and great
On getting things like what we used in Chiney for our bait.
You know them squids and stuff we tried for catching them there conger?
Well, it's the same; but then the name is many a fathom longer.
They seems to me to make a deal and show a great surprise
At things we've seen, Bill, many times, when first they meet their eyes.
Perhaps its 'cos the thing's alive their fancies somewhat tickle,
They only having seen them home screwed up in brine or pickle.

I've told yer how we sounded, now I'll tell yer how we druge,
And if my life's a angel's I'll leave yer for to judge.
We hangs the drege at the yard-arm to a sort o' kind of buffer—
At explernation, Bill, yer no I always was a duffer—
It aint a bad doge neither; for when its pulled it streches
And gives a kind of surge when the dredge at summat ketches;
It's like a koncertina, Bill, but where the wind is squoze,
From end to end a set of stays like Inde rubber goes:
A block is tacked at bottom and through it runs the line—
Which is the werry bane of life to this old pal of thine;
I've burnt my hands, I've spiled my close, I torn my underneath,
I bark'd my shins and nik'd my back, and loosened all my teeth—
All through that blessed line, Bill, which, trifling as it seems,
Is wuss nor all the nightmares that ever hunts in dreams.
The care that is required for to keep that line from breakin'
If your stationed near the donkey is a awful undertakin';
The thing flies thro' your fingers, and if stationed near the drum,
Its safe to nab you somehow by a finger or a thumb;
Then there's the pipe and others, Bill, that raise a shout, and call

* Row.

Till you'd almost think they'd been and caught the devil in the trawl;
The trawl's for fancy drugin' and the work's about the same,
The only diff'rance I can see is that wot's in the name.

A scientifick genelman, our Genius on the cruise,
Explained to us the hanimals, their habits, and their use;
I don't tumble to it much; but, Bill, he spun a yarn
About the objeck of the cruise which I was glad to larn.
He said 'twas for the good of man to raise him summat higher,
Since it was proved by some one that a monkey was his sire;
I don't see how it follers—but he sed from wat he found
There was fields of blazing sea weed below upon the ground;
And every little blessed thing we druge out of the sea
Was for the good of all mankind, including u and me.
He likewise said, and bid us all partikilarly remark,
That at the bottom also 'twas most exceedin' dark,
Cause from twenty million fathoms once we got a curus prize
(He didn't want 'em in the dark) a fish with many eyes.
He told us that we'd all be dooks when this 'ere cruise is done;
I think he was mistaken, or he meant he would be one.

Thare goes the pipe, my hearty; so I'll no more at present write
But ax you to believe yours most faithful

JACK SKYLIGHT

THE COMMON FROG*

X.

The Nervous System of the Frog.

THE nervous system consists of the brain, spinal marrow, and nerves.

The whole consists of a soft, white substance, ultimately composed of minute threads, termed *nerve-fibres*, and minute round bodies called "ganglionic corpuscles."

The brain is contained in the cavity of the skull, and consists of a rounded mass made up of corpuscles and fibres, and itself contains a cavity which is a remnant of the original canal formed by the upgrowth and overclosure of the walls of the primitive groove of the embryo.

The spinal marrow (as has been said earlier), traverses the canal formed by the successive neural arches of the vertebræ being directly continuous with the brain which it, as it were, continues on down the back. Like the brain, it is largely composed of corpuscles, as well as fibres, and itself contains a longitudinal cavity (continuous with that in the brain), which is also the ultimate condition of the canal formed from the primitive embryonic groove.

The nerves generally (which are made up of fibres) proceed forth from the brain and spinal marrow, which therefore are called the *central*, or (from their position along the dorsal axis of the body), the *axial* portion of the nervous system.

All the nerves which so proceed together constitute what is called the *peripheral*, or (because going to the limbs which are appendages of the trunk), the *appendicular* portion of the nervous system.

From the brain proceed the nerves of special sense: a pair, one on each side, going to the nostrils (1, the *olfactory nerves*), another pair going to the eyes (2, the *optic nerves*), and a third pair going to the ears within the skull (3, the *auditory nerves*). Other nerves go to the tongue and palate, ministering to taste, and again others to the little muscles (orbital muscles), which move the eyeball in various directions, and to different parts of the face.

The nerves which come forth from the spinal marrow are called spinal nerves. They proceed out in pairs (one on each side), and are distributed to the limbs and trunk.

Each nerve consists of fibres, of the sorts proceeding respectively from the ventral (in man anterior), and the dorsal (in man posterior) aspects of the spinal marrow. But these two kinds of fibres are distributed side by side in the ramifications and distributions of each nerve.

* Continued from p. 266.

The fibres which come ultimately from the dorsal aspect of the spinal marrow are those which carry inwards the effect of a stimulus applied towards their ultimate termination, and are therefore called *afferent*, or *sensory*.

The fibres which come ultimately from the ventral aspect of the spinal marrow, are those which carry an influence outwards, and produce a contraction in the muscles, and are therefore called *efferent* or *motor*.

It is the nervous system of the Frog, rather than any other set of its organs, which has especially excited interest and attention. It is especially to the relations *inter se*, of the parts of this system that inquiry has been directed. The relations, that is, of its central or axial portion (the brain and spinal column) to its peripheral or appendicular portion (the nerves of the body and limbs).

In the ever memorable year 1789, Galvani accidentally discovered in the separated legs of certain Frogs, prepared for broth, those motions produced by irritation of the exposed great nerve of the thigh, now so familiar to most. This action was long called galvanism, after this observer, not, however, that he was absolutely the first to notice a fact of which he was but a re-discoverer—Swammerdam as long ago as 1658 having observed such motions.

They are generally considered as demonstrating the purely "reflex action" of the nervous system—the responsive action, that is, upon muscles, of nervous centres acted on by external stimuli without the intervention of sensation.

It is affirmed that not only will a decapitated frog endeavour to remove an irritating instrument by means of its hind legs and feet; but that if a caustic fluid be applied to a spot easily reached by one foot, the decapitated frog will apply that foot to the spot. More than this, if that foot be cut off it will move the stump as before, seeking to reach the spot, and failing so to do, will then apply the other foot to the irritated locality.

These, and such experiments, are of course conclusive, if the common assumption be conceded that the brain is the indispensable nervous instrument of sensation.

It may be, however, that the faculty of sensation may be subserved by the spinal cord without the brain, and if so, all these much vaunted experiments are valueless as regards the proof of pure reflex action, not but that they are of extreme interest, as showing what may be done in lower animals without the intervention of any brain action whatever.

Mr. G. H. Lewes has long contended against the attribution of sensation to the brain exclusively, and Dr. Bastian has recently supported and enforced similar views.

The latter remarks in his "Beginnings of Life,"—"instead of accepting the popular view, that the brain is the organ of mind, I believe it would be nearer the truth to look upon the whole nervous system as the organ of mind."

Dr. Bastian here uses the word "mind," not as denoting a rational intellect but as a generic term equivalent to psychical activity.

It may be remarked in passing that these views of Messrs. Lewes and Bastian closely approximate, as far as they go, to that most rational belief that the soul of every creature is whole and entire in every atom of its bodily structure so long as the latter preserves its integrity and vital activity.

The brain of the frog consists of the same essential parts as does the brain of all the vertebrate animals, including man. In the form and in the proportions of those parts, however, it differs extremely from the higher animals (and above all from man) and resembles the lower forms—the brain of the frog (and of Batrachians generally) offering a much closer resemblance to that of a lizard than to that of a mammal.

The brain of man consists of the following fundamental parts:

1. A pair (one on each side) of small rounded bodies, each connected, by a long stalk, with the mass of the brain,

and each shaped somewhat like a life preserver. These are the "*olfactory* lobes," and from the swollen head of each proceed the delicate nerves of smell.

2. An enormous pair of folded masses which form the great bulk of the human brain and are called the *cerebral lobes* or hemispheres. These are so large and preponderant in man, as to hide every other part of the human brain when that organ is viewed from above.

3. A relatively very small portion, but one easily recog-

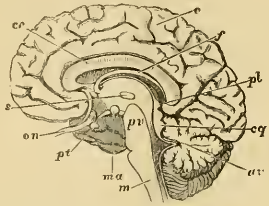

FIG. 69.—The Brain as seen when a Vertical Longitudinal Section has been made through its middle. *Av*, arbor vitæ of the cerebellum; *c*, cerebrum; *cc*, corpus callosum; *cq*, corpora quadrigemina; *f* fornix (between the fornix and the corpus callosum is the septum lucidum); *m*, medulla oblongata; *ma*, corpus mammillare; *on*, optic nerve; *pl*, pineal gland; *pt*, pituitary body; *pv*, pons Varolii; *s*, soft, or middle commissure.

nised since it supports two conspicuous little bodies. One of these (Figs. 69, 70, 71, *pl*) is called the *pineal gland*, and projects more or less upwards; the other (Figs. 69, 70, 71, *pt*) projects downwards and is called the *pituitary body*.

4. An also very small portion relatively, is distinguished by bearing certain small prominences (Fig. 69, *cq*, and Fig. 70, *na* and *te*) placed behind the pineal gland, and called *corpora quadrigemina*.

5. A rounded mass of finely folded brain-substance, placed at the lower part of the back of the head beneath the hinder portion of the cerebral hemispheres. This is

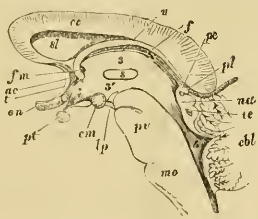

FIG. 70.—Enlarged and Diagrammatic View of a Vertical Section carried through the Corpus Callosum and the parts below. *ac*, anterior commissure; *cc*, corpus callosum; *cbl*, cerebellum; *cm*, corpus mammillare; *f*, fornix; *fm*, foramen of Monro; *i*, infundibulum; *lp*, locus; perforatus medius; *mo*, medulla oblongata; *na*, nates; *on*, optic nerve; *pc*, posterior commissure; *pv*, pons Varolii; *pl*, pineal gland; *pt*, pituitary body; *s*, soft, or middle commissure; *sl*, septum lucidum; *t*, lamina terminalis; *te*, testes; *v*, velum interpositum (between it and the fornix is a space enclosed by the folding over of the cerebrum upon the roof of the third ventricle); 3, upper, and 3', lower part of third ventricle; 4, fourth ventricle—between them is the *iter a tertio ad quartum ventriculum*.

called the *cerebellum*, and when cut through exhibits singular, radiating, tree-like markings, due to the infoldings of the surface of the organ, and called the *arbor vitæ* (Fig. 70, *av*).

6. That part which directly continues the brain into the spinal marrow (Fig. 71, *m*). It is overlapped by the cerebellum, and contains that portion of the remnant of the primitive nervous canal, which is named the *fourth ventricle*. This sixth fundamental part of man's brain is called the *medulla oblongata*.

On turning to the brain of the frog from that of man it is at first sight difficult to find out the resemblances, and to determine which portions of the one answer to definite regions of the other.

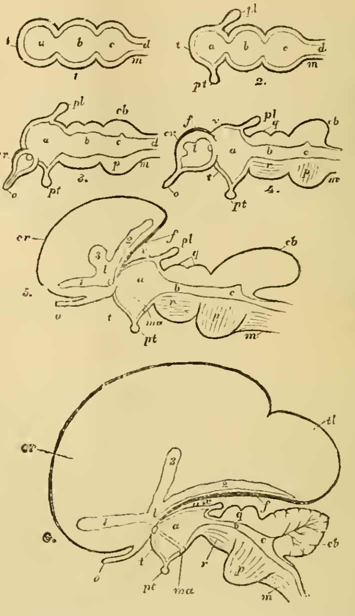

FIG. 71.—Diagram illustrating the progressive Changes that take place during successive stages of the Development of the Brain. 1. The brain in its very early condition, when it consists of three hollow vesicles the cavity of which is continuous with the wide cavity (*d*) of the primitive spinal marrow (*m*). The brain substance forms an envelope of nearly equal thickness throughout. 2. Here the first vesicle or fore-brain has developed the pineal gland (*pl*) above and the pituitary body, (*pt*) below. The wall at the anterior end of the first vesicle (or fore-brain) is the lamina terminalis (*t*). 3. This figure shows the cerebrum (*cr*) budding from the first vesicle, its anterior part (*o*) being prolonged as the olfactory lobe (the so-called olfactory nerve), the cavity of the cerebrum (or incipient lateral ventricle) communicating with that of the olfactory lobe in front and with that of the first cerebral vesicle (third ventricle) behind. The latter communication takes place through the foramen of Monro. The walls of the three primitive vesicles are becoming of unequal thickness, and the cavity (*b*) of the middle vesicle (*iter a tertio ad quartum ventriculum*) is becoming reduced in relative size. 4. The cerebrum is here enlarged, and the inequality in thickness of the wall of the primitive vesicle is increased. The thickened upper part of the wall of the cerebrum is the fornix (*f*). 5. This figure shows the cerebrum still more enlarged, and with a triradiate cavity (*l*, 1, 2, 3). The fornix has now come to look slightly downwards; dotted lines indicate the downward extension of its anterior part, into the corpora mammillaria. 6. Here the cerebrum is still more enlarged and backwardly extended. The fornix is shown bordering the descending cornu and extending into the temporal lobe (*tl*) of the cerebrum, which lobe is destined to descend (when the brain is fully developed) so much more that it comes to advance forwards. The fornix borders the margin of the very thin outer wall of the descending cornu, which when torn forms the fissure of Bichat. The bending back of the cerebrum has now almost enclosed (between the fornix and the velum) the space (*x*) which in Fig. 4 is widely open, making what is morphologically called the outside of the brain come practically to be in its very centre. *a*, fore-brain; *b*, mid-brain; *c*, hind-brain; *cb*, cerebellum; *cr*, cerebrum; *d*, cavity of the medulla; *f*, fornix; *l*, lateral ventricle; *m*, medulla oblongata; *ma*, corpora mammillaria; *o*, olfactory lobe; *p*, pons Varolii; *pl*, pineal gland; *pt*, pituitary body; *q*, corpora quadrigemina; *r*, crura cerebri; *t*, lamina terminalis; *tl*, temporal lobe of the cerebrum; *x*, space, enclosed by the extension backwards of the cerebrum; 1, anterior cornu of lateral ventricle; 2, its middle or descending cornu; 3, its posterior cornu.

In the earliest conditions of the human brain the resemblance is much more marked and obvious; it is later

that the correspondence between the brain of the frog and that of man becomes so disguised through the unequal growth of different portions of the organ in the human brain as it advances in its growth and development. The same six successive portions, however, exist in each.

1. In the frog the olfactory lobes acquire a much larger relative size, and they retain permanently an internal cavity which exists only transitorily in man.

2. The cerebral lobes (or hemispheres) exceed those just noticed but are insignificant indeed, when compared with the corresponding human structures. They may, however, be more insignificant than in the frog, as, for example, in the lamprey, where they are actually smaller than the olfactory lobes. In that the cerebral lobes of the frog each contain a cavity (the lateral ventricles) they have a character which is constant in all animals above fishes, they open by a common aperture (foramen of Monro) into the cavity of the next brain segment behind.

3. This third segment retains a great relative magnitude compared with that of man.

4. The fourth segment, however, consisting of the optic lobes, attains a still further relative development, though consisting only of two bodies instead of four, but these contain a cavity not found in the corpora quadrigemina of the human brain.

5. The fifth segment, the cerebellum, is very small, and

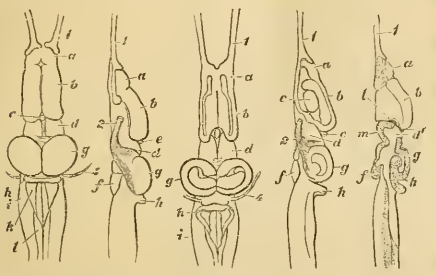

FIG. 72.—Brain of Bull Frog in various views 1, Dorsal view. 2, Lateral view; 3, Transverse horizontal section showing the cavities of the olfactory cerebral and optic lobes. 4, Longitudinal section a little to the left of the median line. 5, Longitudinal section in median line. The corpus striatum, *c*, is here exposed to view and also a body, *g*, within the optic lobes. 5, Longitudinal section in median line. In all five figures:—1, Olfactory nerve; 2, optic nerve; 4, auditory nerve; *a*, olfactory lobe; *b*, cerebral lobe; *c*, corpus striatum; *d*, optic thalamus; *e*, pineal gland; *f*, pituitary body; *g*, optic lobes; *h*, cerebellum.

smaller than the same part in animals both higher and lower in the scale; indeed, in the frog class, this organ may be said to be at its minimum. When cut it exhibits no trace of an *arbor vitæ*.

This fact has a special interest as bearing on alleged functions of this portion of the brain.

It has been asserted by some that the cerebellum ministers to the sexual functions, by others that this part coordinates and directs locomotive movements, and, quite lately, that it is related to movements of the eyes.

The first two of these hypotheses seem to be completely overthrown by our frog. In the first matter there is anything but a deficiency of energy and activity, and as to the second, many reptiles are less active and continuous than the frog in their locomotive efforts. As to the third hypothesis, it should be remembered that the eyes of the Frog are large and very moveable, as also that they require a power of ready adjustment to enable the animal to secure its insect prey.

6. The sixth and last segment of the brain, the medulla oblongata, is also relatively large, and is exposed to view through the rudimentary development of the cerebellum which, as has been said, overlaps it in man.

It has been already said, that in man and the higher animals there are nerves supplying the orbital muscles and different parts of the face.

The eyeball in man is moved by six little muscles, four straight, (the *recti*) and two *oblique*, one being the upper, the other lower, oblique.

Now a nerve called the *third*, because it follows the first two (olfactory and optic) goes from the brain to all the orbital muscles except the upper oblique and the outer rectus.

Another nerve, the *fourth*, proceeds to the upper oblique muscle only.

The *fifth nerve* is a very large one, and supplies the nose, tear-gland, eyelids, upper and lower jaws, tongue and teeth.

The *sixth nerve* is a very small one indeed, being exclusively applied to the outer rectus muscle of the orbit.

The *seventh nerve* is, in part, the auditory nerve in part it sends fibres to the face.

The *eighth nerve* is a very complex structure, and consists of, at least, three nerves united together, all arising from the medulla oblongata. It sends branches to the parts about the throat, as well as to the organ of voice, to the lungs, the stomach and the heart.

The nerves of the frog exhibit certain intermediate conditions like those we have seen to exist in various other parts of its anatomy.

In the higher vertebrate animals, as in Man, the

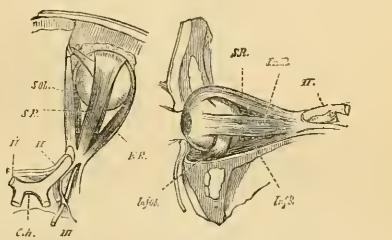

FIG. 73—The Muscles of the Eyeballs, viewed from above and from the outer side. *R.S.*, the superior rectus; *Inf.R.*, the inferior rectus; *E.R.*, the external rectus; *In.R.*, the internal rectus; *S.Ob.*, the superior oblique; *Inf.Ob.*, the inferior oblique; *Ch*, the chiasma of the optic nerves (*II.*); *III.*, the third nerve, which supplies all the muscles except the superior oblique and the external rectus.

muscles which move the eye-ball are supplied by three distinct nerves termed respectively the 3rd, 4th, and 6th. The 5th nerve being a very large and complex one, sending branches to various parts of the head and its organs.

Now in the frog there is no distinct 6th nerve, it being replaced by an extra branch of the 5th nerve. This modification, however, is but one step towards a condition which obtains in the Mud-fish (*Lepidosiren*), when all these three nerves are quite blended with one division (the Ophthalmic) of the fifth nerve.

Again in the higher Vertebrates, as in Man, the 8th nerve is a very large and complex one, and distributed as in him. It is also so distributed in the adult frog.

In the tadpole, however, this nerve shows a very different arrangement. After issuing from the skull this nerve sends a branch down the outer side of each branchial arch and then gives off a very long one, which extends laterally, *i.e.* along the side of the body and tail.

Nothing like this exists in any Beast, Bird or Reptile, but when we come to the class of Fishes we encounter a precisely similar state of things. Here we find the eighth nerve sending a branch to each branchial arch, and giving off a great nerve proceeding along the side of the body and tail, and on that account named the *nervus lateralis*.

(*To be continued.*)

THE INDUCTION TUBE OF W. SIEMENS

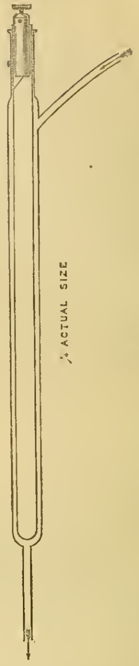
A TRANSLATION from a French periodical, *La Nature*, of an article on "Tubes for silent electrical discharges," appears in NATURE of Jan. 29 (vol. ix. p. 244). After referring to the action of the electric spark upon oxygen gas, the author of the article continues: "For the purpose of more easily obtaining ozone, M. Houzeau has recently constructed an apparatus worked by a Ruhmkorff coil, in which there are no longer sparks, but only dark discharges—*effluvia*—far more efficacious in the production of modified oxygen." Again, it is said, that M. Houzeau "has recently devised an apparatus for the preparation of ozone, which is spreading rapidly among the laboratories, and which has already yielded very remarkable results." A description of the apparatus is then given; further on, it is said, that "M. Houzeau is not the only one who has made use of the tubes whose structure he has made known, but that M. Boillot, a writer, it appears," well known to the readers of the *Moniteur*, "has made some further propositions about them; and lastly, that M. A. Thénard" (whose investigations constitute the main subject of the article) "has brought to bear on the construction of the tubes a further modification which makes them still more efficacious." A description and drawing of the apparatus of M. A. Thénard is given. Those who are unacquainted with the facts of the case will be surprised to learn that the invention thus publicly announced, although, doubtless, in principle deserving of the highest praise, was not made either by M. Houzeau, M. Boillot, or M. A. Thénard, but is simply a somewhat clumsy form of the Induction-tube devised by W. Siemens, which is described in his "Memoir on Electrostatic Induction," contained in *Poggendorff's Annalen*, for 1857 (vol. cii. p. 120).

This Induction-tube is one of the most remarkable, as well as simple instruments, of chemical research which has ever been devised; enabling us, by the action of electricity, to effect changes in the composition of gases which may be compared with the chemical changes effected in liquids by the agency of the voltaic battery. A few words in explanation of the instrument may interest the readers of NATURE.

The simplest form of induction-apparatus consists in two thin glass plates, of which one side is coated with tin-foil, and which are so arranged that the uncovered surfaces are parallel to one another, and separated by a uniform, narrow interval of about one or two millimetres filled, say, with air. If this apparatus be charged with electricity by a sufficiently charged Leyden jar, at the moment of the charge the air between the plates becomes luminous, and the same appearance is presented when the apparatus is discharged. To produce this effect, however, the apparatus must be charged beyond a certain limit, determined, in each case, by the special arrangement of the apparatus and the materials employed in its construction. Now, if the two plates of tin-foil be respectively connected with the terminals of a powerful Ruhmkorff's coil, the apparatus is successively charged with electricity and discharged; these operations being alternately repeated in such rapid succession that the air, in the interval between the plates, appears permanently luminous. We have, moreover, evidence of the occurrence in this interval of chemical changes determined by the electric action, in the odour and characteristic properties of ozone which may be recognised in a current of air or oxygen compelled to pass between the plates. The conclusion drawn by Siemens from this experiment is, that the electric polarisation of the particles of a dielectric cannot be carried beyond a certain point; and that if it be attempted to accumulate electricity in the apparatus beyond this point, the excess of this tension or polarisation appears in the form of the dynamical phenomena occurring between the plates, namely, light, heat, and chemical change. (*Poggendorff's Annalen*, *loc. cit.*, p. 119).

Now it is evident that in this arrangement the two sheets of glass may be replaced by two concentric cylinders of glass, the interior of the inner cylinder and the exterior of the outer cylinder being coated with tin-foil, as in the case of the plates. It is precisely this change which is effected in the induction-tube of Siemens, but with the additional advantage that in the induction-tube a regular flow of the gas to be operated upon may be maintained, that the experiment may be made at any required temperature, and the gaseous products of the experiment collected for examination. The construction of this induction-tube will be readily understood from the annexed drawing (taken from *Pogg. Ann.* loc. cit.), where the ring shows the horizontal section of the tube.

6.a



1/4 ACTUAL SIZE

6 b

2/5 ACTUAL SIZE

If the reader will be at the trouble of comparing the description of the tube of M. Houzeau and the drawing of the tube of M. A. Thénard, with the description and drawing of the induction-tube of Siemens he will be satisfied of the substantial identity, both in principle and construction, of these pretended novelties with that invention. At the same time if the statement of these ridiculous pretensions were limited to those made in the article translated in NATURE, vol. ix. p. 244, they would hardly be worthy of notice, but this is not quite the case. The induction-tube of Siemens under the title of "the tube of M. Houzeau," is being rapidly acclimatised as a French discovery. In the article on ozone contained in a recent number of the "Dictionnaire de Chimie," which bears evidence of being the work of a highly competent writer, where we might expect to find a comprehensive treatment of the subject, a similar lapse occurs. We have there, too, a drawing of the tube of M. Houzeau, which is described as "a happy modification of the tube of M. Babo," but not a word is said about Siemens, the inventor of the tube, whose name is simply dropped. Other similar instances might be brought forward which have afforded an opportunity of rectifying these mistakes, but of which no advantage has been taken. I have therefore ventured to make these remarks, not only I may say in the interest of justice, but also, having myself made many experiments with the induction-tube of Siemens, I have learned, perhaps, more than others to appreciate its value and feel myself under a special debt of gratitude to the inventor.

B. C. BRODIE

RECENT RESEARCHES ON TERMITES AND HONEY-BEES

THE accompanying letter, just received from Fritz Müller, in Southern Brazil, is so interesting that it appears to me well worth publishing in NATURE. His discovery of the two sexually mature forms of Termites,

and of their habits, is now published in Germany; nevertheless few Englishmen will have as yet seen the account.

In the German paper he justly compares, as far as function is concerned, the winged males and females of the one form, and the wingless males and females of the second form, with those plants which produce flowers of two forms, serving different ends, of which so excellent an account has lately appeared in NATURE by his brother, Hermann Müller.

The facts, also, given by Fritz Müller with respect to the stingless bees of Brazil will surprise and interest entomologists. CHARLES DARWIN

Feb. 11

"For some years I have been engaged in studying the natural history of our Termites, of which I have had more than a dozen living species at my disposition. The several species differ much more in their habits and in their anatomy than is generally assumed. In most species there are two sets of neuters, viz., labourers and soldiers; but in some species (*Calotermes* Hg.) the labourers, and in others (*Anoplotermes* F. M.) the soldiers, are wanting. With respect to these neuters I have come to the same conclusion as that arrived at by Mr. Bates, viz. that, differently from what we see in social Hymenoptera, they are not modified imagos (sterile females), but modified larvæ, which undergo no further metamorphosis. This accounts for the fact first observed by Lespès, that both the sexes are represented among the sterile (or so-called neuter) Termites. In some species of *Calotermes* the male soldiers may even externally be distinguished from the female ones. I have been able to confirm, in almost all our species, the fact already observed by Mr. Smeathman a century ago, but doubted by most subsequent writers, that in the company of the queen there lives always a king. The most interesting fact in the natural history of these curious insects is the existence of two forms of sexual individuals, in some (if not in all) of the species. Besides the winged males and females, which are produced in vast numbers, and which, leaving the termitary in large swarms, may intercross with those produced in other communities, there are wingless males and females, which never leave the termitary where they are born, and which replace the winged males or females, whenever a community does not find in due time a true king or queen. Once I found a king (of a species of *Eutermes*) living in company with as many as thirty-one such complemental females, as they may be called, instead of with a single legitimate queen. Termites would, no doubt, save an extraordinary amount of labour if, instead of raising annually myriads of winged males and females, almost all of which (helpless creatures as they are) perish in the time of swarming without being able to find a new home, they raised solely a few wingless males and females, which, free from danger, might remain in their native termitary; and he who does not admit the paramount importance of intercrossing, must of course wonder why this latter manner of reproduction (by wingless individuals) has not long since taken the place through natural selection of the production of winged males and females. But the wingless individuals would of course have to pair always with their near relatives, whilst by the swarming of the winged Termites a chance is given to them for the intercrossing of individuals not nearly related. I sent to Germany, about a year ago, a paper on this subject, but do not know whether it has yet been published.

"From Termites I have lately turned my attention to a still more interesting group of social insects, viz., our stingless honey-bees (Melipona and Trigona). Though a high authority in this matter, Mr. Frederick Smith, has lately affirmed, that "we have now acquired almost a complete history of their economy," I still believe, that almost all remains to be done in this respect. I think that even their affinities are not yet well established, and that they are by no means intermediate between hive- and humble-bees, nor so nearly allied to them, as is now generally admitted. Wasps and hive-bees have no doubt independently acquired their social habits, as well as the habit of constructing combs of hexagonal cells, and so, I think, has Melipona. The genera Apis and Melipona may even have separated from a common progenitor, before wax was used in the construction of the cells; for in hive-bees, as is well known, wax is secreted on the ventral side: in Melipona on the contrary, as I have seen, on the dorsal side of the abdomen; now it is not probable, that the secretion of wax, when once established, should have migrated from the ventral to the dorsal side, or *vice versâ*.

"The queen of the hive-bee fixes her eggs on the bottom of the empty cells; the larvæ are fed by the labourers at first with semi-digested food, and afterwards with a mixture of pollen and honey, and only when the larvæ are full grown, the cells are closed. The Meliponæ and Trigonæ, on the contrary, fill the cells with semi-digested food before the eggs are laid, and they shut the cells immediately after the queen has dropped an egg on the food. With hive-bees the royal cells, in which the future queens have to be raised, differ in their direction from the other cells; this is not the case with Melipona and Trigona, where all the cells are vertical, with their orifices turned upward, forming horizontal (or rarely spirally ascending) combs. You know that honey is stored by our stingless bees in large, oval, irregularly clustered cells; and thus there are many more or less important differences in the structure, as well as in the economy, of Apis and Melipona.

"My brother, who is now examining carefully the external structure of our species, is surprised at the amount of variability, which the several species show in the structure of their hind legs, of their wings, &c., and not less are the differences they exhibit in their habits.

"I have hitherto observed here 14 species of Melipona and Trigona, the smallest of them scarcely exceeding 2 millimetres in length, the largest being about the size of the hive-bee. One of these species lives as a parasite within the nests of some other species. I have now, in my garden, hives of 4 of our species, in which I have observed the construction of the combs, the laying of the eggs, &c., and I hope I shall soon be able to obtain hives of some more species. Some of our species are so elegant and beautiful and so extremely interesting, that they would be a most precious acquisition for zoological gardens or large hot-houses; nor do I think that it would be very difficult to bring them to Europe and there to preserve them in a living state.

"If it be of some interest to you I shall be glad to give you from time to time an account of what I may observe in my Melipona apiary.

"Believe me, dear Sir, &c.,

"FRITZ MÜLLER"

*MARS**

IN the previous article were mentioned some of Professor Kaiser's conclusions. We are induced to add a few further remarks, from their general applicability. The delineation of the heavenly bodies, he says, is always a very difficult task, especially when, as in the case of Mars, we have to deal with features more or less indistinct, delicately and gradually shaded. With the most powerful telescopes the disc is but small; and on it we find a mass of ill-defined and frequently very feeble spots, which require close attention for their disentanglement, and it is hard to obtain a clear conviction as to the outlines and shadings that have to be drawn. The difficulty is much increased by the inces-

* Continued from p. 289.

sant undulations of the air; and in the seldom-recurring moments of stillness so much under good circumstances is visible, that even the best artist cannot draw it all in half an hour, a period during which usually there are but a very few tranquil glimpses, and after which the planet will have materially changed its aspect from rotation. Even were it easier to distinguish what is actually visible, it requires great practice to represent it faithfully; and whoever has had personal experience of the difficulties of such designs will have but a limited confidence in the various portraits or the supposed changes that they represent. As a further illustration of these difficulties he refers to the representations of the Orion nebula by Rosse, Lassell, Secchi, and Liapounov (he could have added Herschel II.); or the portraits given by Bond, and others, of Donati's Comet. He might have cited, had he known of it, Prof. Young's remark as to the solar corona (where, however, these difficulties are heightened by the excitement of the moment), that "the drawings made by persons standing side by side differ to an extent that is sometimes really ludicrous, and has induced more than one astronomer who had not himself seen an eclipse, but judged only from the written accounts and sketches, to declare his belief that this whole outer corona is a mere subjective phenomenon."

The justice of Kaiser's remarks will readily make itself felt, but they do not exhaust the subject; something may perhaps be added as to the "personal equation" of vision. Independently of mechanical defects in the eye, there are inaccuracies of perception; and even if the rays have kept an uninterrupted and undeviating course to the retina, they do not always produce corresponding impressions on the mind. Whatever may be the cause, we frequently meet with defects in the sense of form, or proportion, or inclination, or even the presence of features which are not the immediate objects of attention. Comparisons of size are often very erroneous; craftsmen well know the meaning of "a true eye;" and the expression "I did not see it," is constantly employed with reference to a thousand objects whose representation on the retina is all the while unquestionable. It is in these respects that celestial photography is invaluable as recording everything and putting everything in its proper place; but photography, as Kaiser observes, is inapplicable to the light of Mars. Another point, too, might have admitted of notice. Although we may certainly, with him, be baffled in reconciling Rosse and Lassell, we may bear in mind, as regards the comparison of larger and smaller instruments, Dawes's important remark to the effect that a certain relative proportion of light and power may be essential to the visibility of some classes of difficult objects.

Without subscribing implicitly to the whole of Kaiser's views, some of which admit of doubt—as, for instance, when we contrast his assertion that the spots are never sharply defined, with the clearness and keenness of outline occasionally recorded by Lockyer and others—we may well admit their general accuracy. But we find it more difficult to accompany him in his inferences as to the planet's physical constitution.

The earth-light upon the moon having been found by Schröter more conspicuous when it proceeded from the hemisphere of our globe containing the largest amount of land, Kaiser implies that it has hence been inferred that (as it is difficult for us not to imagine other planets constituted like our own), the brighter and darker portions of Mars are equivalent to land and water. Whether such an opinion may have been arrived at in this circuitous way or not, it seems highly probable without any reference to lunar appearances. The eminently absorptive power of water is well known; even a thickness of seven feet will, it is said, diminish the incident light by one-half; and below 700 feet it is quenched in unbroken darkness; and the quantity of diffused light reflected from its surface would be inconsiderable, while the solar image at the distance of the Earth would be too minute, in all probability, to be visible. This reasoning would seem fairly to hold its ground against that of the Leiden astronomer, who does not believe that seas so looked upon would show such innumerable gradations in tone, or be so invariably ill-defined at their edges, while the same telescope gives perfect sharpness to the polar snows. He goes in fact so far as to say that if we may form any conclusion from their aspect, it is, that they cannot resemble seas such as our own. But as to distinctness of boundary, his experience is not accordant with that of other excellent observers, especially Lockyer, who remarks that "the effect of a cloudless and perfectly pure sky both here and on Mars appears to be, that the dark portions of the planet become darkest and most distinctly visible; the coastlines (if I may so call them) being at such times so hard and sharp that (as has been mentioned by Mr. Lassell) it is quite impossible to represent the outlines faithfully." A more natural inference, it seems to the writer, would be that these fluid masses contain large areas of very slight depth, that the edges are in many places very shelving, and that possibly they may be the more transparent from the absence of salt. Other astronomers, Kaiser tells us, but without mentioning their names, have reversed the idea, and thought the bright parts to be seas, but they do not thus escape his objections on the score of definition, nor account for the dusky tracts which some of the great bright expanses contain. He has perhaps got hold of a more substantial difficulty in the aspect of the north polar region, where the white spot is often encompassed by a widely-extended dark zone with many gradations of tint. The width of this belt, very great when foreshortening is taken into account, is no doubt variable: Beer and Mädler ascribed it to the non-reflective power of the damp surface bared by the rapidly melting snow. On the whole, when Kaiser considers that nothing is established with certainty but the existence of an atmosphere and the connection of the polar spots with the seasons, we hesitate to follow him; and we should prefer the conclusion of Phillips, adopted by Lockyer, that "over a permanent basis of bright and dusky tracts, a variable envelope gathers and fluctuates, partially modifying the aspect of the fundamental features, and even in some degree disguising them under new lights and shades, which present no constancy, a thin vaporous atmosphere probably resting on a surface of land, snow, and water." A more protracted course of observation may possibly modify in some way this result, but so far as past investigations extend, we may say that nothing has been detected inconsistent with it. Could we be actually transported to that far distant surface, we should probably find much to astonish us that we cannot so much as conjecture here; it was a sound remark of Schröter's that unity in variety is the universal character of creation; and the spectroscope of Huggins has already in this instance confirmed it by the detection of absorption-lines the cause of which is utterly unknown. Our future inquiries should be conducted in that impartial spirit which is equally ready to admit the indications of discrepancy and of resemblance, and which is more anxious to ascertain facts than to seek their premature elucidation. We have as yet read but a part of the inscription on that golden shield: some of it has probably been deciphered correctly; how much of the remainder may give way we know not; but the whole, it will never be given to us to understand.

The extensive researches in which Dr. Terby of Louvain has for some time been engaged, and in which he has shown unwearied diligence and perseverance, if embodied, as we trust they will be, in one comprehensive result, will give material assistance in disentangling and concentrating our present scattered and discordant materials, and we may look forward with hope to the very

promising opposition of 1877; when, if the seasons on both planets are as favourable as their mutual proximity, we may reasonably expect some advance to be in store for us. The great object will naturally be the identification of the dark spots, as well as a more careful delineation of their boundaries: attention will doubtless be paid towards obtaining a definitive value for the rotation; but in this direction progress is not very material, as we have already a sufficient approximation. Those who would see an extraordinary instance of the most painstaking and protracted efforts to get rid of a trifling uncertainty may apply themselves to the 23 pages of Kaiser, in which all kinds of varied combinations are tried to reconcile some conflicting decimals of a second, for to these the question is reduced at last. Cassini, as far back as 1666, had fixed the rotation at 24h. 40m. with surprising correctness for his day. Herschel I. brought it to 24h. 39m. 21·67s. but, as Beer and Mädler perceived, the omission of one rotation, and of the effects of phasis and aberration, vitiated the result. They in turn gave 24h. 37m. 23·7s. Kaiser, from many elaborate comparisons, deduced a mean of 22·62s., but Proctor having found a value of 22·735s. the former, who thought the English astronomer's coincidences illusory, went into the whole subject afresh with marvellous minuteness, and got out a final mean of 22·531s., discovering by the way some unexpected inaccuracies, convincing himself that the correctness of the best drawings has been greatly over-rated, and finally, in much mortified perplexity, leaving it to every one to choose his own combination. No computation, he says, can make us sure to the hundredth of a second; and unless observations become very much more precise, it will be several centuries before such a result will be obtained: how much the wiser mankind would be for it, is another question, which we need not discuss here. But there is, perhaps, no great difficulty in divining the cause of the Professor's troubles. Epochs of rotation could only be safely taken from drawings made with that special object, and few such probably exist; the designer usually either contenting himself with a general likeness, or being occupied about details, the study of which would of itself render him less attentive to mere position. In future, these objects might be better separated; and while the artist busies himself with the *minutiæ* of the picture, the rotation-seeker should employ himself exclusively in estimating the co-ordinates of some conspicuous points—a process which admits of a mean taken between many proportional valuations.

Several other desirable matters of inquiry will readily offer themselves. Measures of ellipticity have as yet yielded only contradictory results. The inclination of the axis, last deduced by Oudemans in 1852, may be susceptible of correction; and the excentric position of one or both of the snow-spots, and the unsymmetrical position of the isothermal poles, would be matters of interesting investigation. The amount of the latter deviation, first measured by the elder Herschel, has been given so very differently by different observers, even at the same opposition, that it evidently is open to fresh determination. The well-known colours will of course catch the eye; and attention may be paid to the question whether the green, or as others think blue, tint of the dark parts (which Kaiser saw as grey only) is really, as Herschel II. implies, the mere result of contrast. The effect may be possibly thus heightened; but no one who saw one of the great seas as the writer did with a 9 in. silvered speculum on April 4, 1871, could doubt the independent existence of a beautiful clear blue-grey tint, the more certain as a shading on another part of the disc was of a brownish hue: nor does it seem to have been noticed that no effect of contrast has been traced in the polar snows. The luminous and occasionally coloured patches and segments on the limb should receive attention, and the position of "Dawes' ice-island" be scrutinised; such a brilliant speck I witnessed at the above epoch, but I believe in another situation. Black points should be looked for, as such have been detected by Mitchell and Dawes; and it should be noted at the time of any conspicuous feebleness of the markings, whether the sharpness of the limb indicates the cause to be further distant than our own atmosphere: and in general the "daily—nay, hourly—changes in the detail and in the tones of the different parts of the planet, both light and dark," described by Lockyer, should be carefully watched and recorded;

"In tenui labor;"

nevertheless, none of these little matters will be considered insignificant by those who love to behold in such things the footsteps of Creative and Upholding Power.

T. W. WEBB

NOTES

WE have received some interesting notes of the work done by the eminent Russian explorer, Dr. von Miclucho-Maclay, which we hope to publish next week. Contrary to the advice of everyone, this intrepid traveller and true devotee of Science is determined upon again visiting the east coast of Papua. When his researches here are complete he intends to visit some of the islands of Polynesia and certain parts of the coast of Australia. This, he calculates, will take up five or six years. The Governor of the Dutch East Indies, like a true man of Science, had given Dr. Maclay, for the last six months, roomy and comfortable quarters in his palace at Buitonrovg. It would be well, if all in high position would imitate this kind of "patronage."

THE Meteorological Committee of the Board of Trade have resolved to commence the issue of lithographed copies of the twenty-four hourly tabulated readings, taken at their seven observatories, for every element which is observed continuously, commencing with January 1, 1874. The sheets will be issued quarterly, and the issue will be a limited one. The subscription for a copy is 1*l*. per annum, to cover a portion of the expense of production. The sheets will not be distributed with the publications of the office.

M. L. QUETELET, the founder and director of the Brussels Observatory, died in Brussels on Monday night, aged 77. He leaves a son, M. Ernest Quételet, who inherits the scientific enthusiasm of his father.

THE letter which has been received from Consul Prideaux, and the extract from Cameron's letter published in the *Academy*, adds but little to the details we gave some time ago concerning Livingstone's reported death. Lake Bemba is identified by Consul Prideaux as Lake Bangweolo, and a letter from the Arab Governor of Unyanyembe fixes the spot where the great traveller died at Lobisa. A letter to Dr. Petermann from the German African traveller and Austrian Consul at Zanzibar, Mr. Richard Brenner, merely repeats the statements already known. Dr. Kirk, under date Feb. 12, writes to the *Academy* as follows:—"This morning I have heard indirectly from Zanzibar, and find people there who could judge, still question the truth of the story of Livingstone's death. Like us, they see nothing but native report to base it on." Let us hope that this is the real state of the case. As Zanzibar and Ujiji are at present at peace it is expected that there will be no difficulty in getting the Doctor's valuable journals. It is gratifying to see from Mr. Markham's letter in yesterday's *Times* that through Sir Samuel Baker's determined energy, the route to Zanzibar has been virtually opened up from the north.

THE letter above referred to from Consul Brenner, states that a German botanist, M. Hildebrand, has been preparing, for a year past, to undertake a journey into the interior of the Galla country and Somali Land.

A SHORT course of Lectures on the Growth of Physical Science during the last twenty-five years, is to be given at the request of a number of gentlemen in Edinburgh, in St. George's Hall, by Prof. Tait, of the University of Edinburgh. The first lecture is to be given to-day.

AT the Annual General Meeting of the Glasgow Geological Society, on Thursday last, Sir William Thomson gave an address on "The Influence of Geological Changes on the Earth's Rotation." We hope to be able, very soon to give an abstract of this address.

THE *Times* announces that the following arrangements have been made in consequence of Mr. Henry Cole's retirement last year from the post of Secretary of the Science and Art Department and Director of the South Kensington Museum:—Sir Francis Sandford, Secretary of the Education Department, will also be Secretary of the Science and Art Department; Major Donnelly, R.E., Official Inspector for Science, will be Director of Schools of Science and Art and affiliated institutions; Mr. Norman MacLeod will remain Assistant Secretary of the Science and Art Department; and Mr. Philip Cunliffe Owen, Assistant Director of the South Kensington Museum, will be the Director of that Museum.

PROF. HELMHOLTZ has communicated to the Academy of Sciences of Berlin a paper on "The Direction of Balloons," in which he enters into a number of elaborate calculations. In his calculations he directs attention only to the relation between the force and the weight, and supposes that the means at our disposal will enable us to construct the envelope of the balloon and its motive power. But, Prof. Helmholtz says, "it appears to me that here there exists a great difficulty in the way of execution, for the solid parts of the machine do not preserve the necessary solidity when they are much enlarged, although they continue to be geometrically similar; they then must be made thicker, and consequently heavier. To obtain the same effect with small motors at great speed, there is a loss of work. We can only work economically then with motors of large surface urged by a motion relatively slow. One of the great practical difficulties will then be to obtain the necessary dimensions without overloading the balloon."

PROF. H. A. NEWTON thus criticises the Report of the British Association Committee on Units in the March number of *Silliman's Journal*:—The *dyne* or unit of force which is proposed by the committee is to be a new unit of the same nature as a gram-weight, or the earth's attraction for a gram-mass, and having no commensurable ratio with it. Now our simplest and most useful ideas of force are derived at once from weight. It seems to us that, of necessity, this will always be the case. Probably the learned committee have no expectation that even among scientific men the new units will entirely replace what they call the vulgar ones. If, then, their recommendation is accepted, we shall create for certain departments of mechanical science new units of force and energy which are in no useful ratios to those used in other departments of science, and by people at large. Is there not some way of avoiding this great evil? Societies are formed and sustained whose main and most worthy object is to get rid of such confusions. We think the proposed units should be stoutly challenged to show a necessity for their being. We do need, it may be added, a new *name* for the earth's attraction upon a gram of matter at some fixed place. The words *gram*, *pound*, *ton*, &c., have had to do service in two different senses, that is, as mass, and as force. If any good word could come into use that shall express the earth's attractive force for a gram of matter at some place that may be agreed upon, it would meet a real want.

THE collection of Humming Birds of the late M. Jules Bourcier is to be sold by auction at Paris on March 2. M. Bourcier's collection of these birds was, a few years ago, the best and most complete in existence, embracing numerous types of the species described by the French naturalists, and specimens collected by himself during his residence in Ecuador as French Consul.

MR. A. S. NAPIER, of Owens College, Manchester, who has been elected to a Natural Science Scholarship at Exeter College, Oxford, received the first part of his science training at Rugby. Mr. W. E. Hoyle, of Owens College, has been elected to a Natural Science exhibition in the same College.

THE Japanese Government have, through their Legation in London, appointed Mr. R. Routledge, B. Sc., F.C.S., to the Professorship of Chemistry and Physics in the Imperial College at Yeddo. Mr. Routledge was formerly of the Owens College, Manchester, where he studied Chemistry under Dr. Roscoe, and afterwards took high honours at the University of London.

WE gladly call attention to the action taken by the British Association, "Boulder Committee," under its secretary, the Rev. H. W. Crosskey. A large printed form has been prepared, with a set of well-drawn up questions, and spaces for the answers of those who may be inclined to assist the Committee in their praiseworthy work. Copies of this form may be obtained by applying to Mr. Crosskey, 28, George Road, Birmingham.

A TELEGRAM from Cairo announces that Dr. Beke has succeeded in discovering the true Mount Sinai. It is said to be situated one day's journey west of Akaba, is called by the Arabs the Mountain of Light, and is 5,000 ft. high. On the summit were some sacrificial remains of animals.

MISS FRANCES STRICKLAND, of Appleby-court, Tewkesbury, has offered to found at the University of Cambridge a curatorship of the Ornithological collection formerly belonging to her brother, Mr. H. F. Strickland, F.R.S., and presented to the University in 1867 by his widow. Miss Strickland proposes to endow the office with a permanent stipend of 150*l*. per annum. The principal conditions attached to the gift are that the curator be appointed by the foundress during her lifetime, and afterwards by Mrs. Catherine Strickland, and, on the decease of these two ladies, by the superintendent of the University Museums of Zoology and Comparative Anatomy, but in each case with the consent of the Vice-Chancellor. That the curator is to be subject to the authority of the superintendent of the museums, and that his first duty be the proper custody and efficient preservation of the Strickland collection, making an accurate catalogue of it, so that the collection be of the greatest service to Science. He would be required to reside in the University; and in case of the abolition of the office of superintendent of the museums the curator shall be appointed and removed by the Professor of Zoology and Comparative Anatomy with the consent of the Vice-Chancellor. The Council of the Senate recommend the acceptance of Miss Strickland's liberal offer.

ON this day week there passed from among us a countryman whose power has been but too little appreciated, and far too little recompensed by ourselves or other European nations. Sir Francis Pettit Smith was, to all intents and purposes, the discoverer of the screw-propeller, a method of progression as practically advantageous as it is theoretically perfect; nevertheless, the benefits which he has derived from his indebted countrymen are but a paltry annuity and an equally insignificant decoration. Considering the little encouragement given by our Government for first-class work, it is really a matter of surprise that any should be produced at all.

At the meeting of the Academy of Sciences at Paris, on Feb. 9, the candidates to be recommended to the Minister of Public Instruction for the chair of Comparative Embryogenesis at the College of France, were balloted for. The names of MM. Gerbe, Balbiani, and Dareste, were presented to the meeting, and the result of the voting was to select the two former gentlemen as the Academy's nominees for the post.

Captain S. P. Oliver writes us concerning a meteor-cloud which he observed at Buncrana, Co. Donegal, on Feb. 5, at about 9.10 p.m. local time. He saw what he at first thought to be a comet's tail, viz. a broad band of silvery white and luminous cloud extending in an arc from S.E. by E. to N.W. by W., as near as he could judge, from horizon to horizon, but tapering towards the extremities. The apex of this arc, which was some four or five degrees in width, was as nearly as possible on the meridian at about 80° elevation from the horizon. The band passed within three or four degrees above the upper stars of Orion. Through this luminous cloud the stars shone brightly. The edges appeared well-marked, and there was no appearance of that serpentine track into which meteor-clouds frequently dissolve. Several "shooting-stars" were visible the same evening. One especially he noticed which seemed to come from a radiant point at the S.E. extremity of the above-named cloud.

Messrs. Smith, Elder, and Co. have a new edition of Mr. Charles Darwin's work on the "Structure and Distribution of Coral Reefs" in preparation.

Michelet, the celebrated historian, who died within the last few days at Cannes, aged 76 years, has written a few sensational books on natural history. "L'Oiseau" and "L'Insecte," had an immense circulation, although their real scientific value was very small.

M. Reinwold, one of the largest Parisian scientific publishers, is just publishing a translation of Haeckel's "History of Creation." It is prefaced by M. Charles Martin, one of the most celebrated correspondent members of the French Institute. Consequently Darwinism is not to be considered as having been extinguished in France by the last rejection of Darwin by the Academy. Neither will the success of Haeckel's great work be paralysed by the cry of *no more Germanism* raised in certain quarters.

Capt. Mouchez, who has been appointed the chief astronomer for St. Paul's station on the Venus Transit Expedition, is publishing, at the expense of the French Admiralty, a map of the Algerian coast on the scale of $\frac{1}{120000}$. The survey was executed on a new plan and only lasted 18 months. Although Algeria extends about 750 miles east-west, M. Mouchez has determined all his stations by a series of triangulations executed on shore, independently of the situation of his boats or ships.

For some years past much interest has been excited in the United States in reference to the erection of a large telescope, and possibly a complete astronomical observatory on the high portion of the Rocky Mountains. As preliminary to this, a number of careful examinations have been made of the optical qualities of the atmosphere in various portions of the Western country. Of these special interest attaches to the expedition of Professor Davidson of the Coast Survey, whose report to the California Academy of Sciences, states that the meteorological tables kept at Summit Station, on the Sierra Nevada, 7,042 feet above the sea, during the year ending November 1867, show that out of 358 days and nights only eighty-eight were cloudy, nearly all of these occurring in the winter months, during which the snowfall was about forty-five feet, the winter not being unusually mild. The summer weather is very pleasant, the nights cool, and the atmosphere wonderfully clear. The mountain flanks are covered with verdure during the summer, and there is freedom from great clouds of dust. Prof. Davidson says that, owing to the steadiness of the atmosphere, observations at this elevated point would in one or two nights be of greater value than the results of six months' observations at lower stations. Higher and perhaps more desirable positions exist in the immediate neighbourhood of Summit Station; and the interest excited by Prof. Davidson's report probably has, to a considerable extent, influenced the determination announced in a recent letter of Mr. J. Lick, the well-known millionaire of San Francisco. This gentleman has indicated in a letter to the California Academy of Sciences, and again in a letter to Prof. Joseph Henry, his desire to establish an observatory in the best possible location, and provide it with the largest and finest astronomical instruments. He proposes to this end to set aside one million dollars as a permanent endowment fund. This is a monument and a renown which few are rich and wise enough to achieve for themselves, and it is greatly to be hoped that the founder of the Lick Observatory may live to enjoy the congratulations of his State and country.

Prof. James Orton, of Vassar College, N.Y., has just returned to the United States from South America, where he has been engaged in a second exploration of the Amazons. The general object of his recent travels in South America, was to supplement his expedition in 1867, when he crossed the continent from west to east, *viâ* Quito and the Nipo wilderness. His route in 1873 was up the Amazons from Para to Yurimaguas on the Hoallaga River; thence up to the Paravapura and its tributary, the Cachiyeen to Balsa Puerto; thence over the Icuto Vange on foot to Moyobamba; thence across and among the Andes to Chachapoyas and Cayamarca, crossing the Upper Mavañon, or Balsas, and striking the coast at Pacasmayo; thence to Lima and its immediate region; thence to Mollendo, Areguipa and Puno on the shore of the Lake Titicaca. He was the first traveller to pass from the Pacific to the Lake by the railway just finished by Mr. Meiggs. The prime object of his explorations was to study the physical geography, geology and topography of the Amazons. On these points he obtained a vast amount of new and reliable information. He found that the Upper Amazon (Marañora), has been grossly misrepresented in all the more recent maps of Peru. He made everywhere, but especially in Northern Peru, large collections in natural history, to throw light upon the distribution of animal life. Prof. Orton will condense the results of his expedition in a work on the Physical Geography, Natural History, and Commercial Resources of the Valley of the Amazons.

Fresh advices to January 11, received from the German exploring expedition in the Lybian Desert, under Gerhard Rohlfs, announce that the expedition had reached the important oasis of Dachel, containing 17,000 inhabitants. Valuable geographical discoveries had been made, and six maps of the country had been taken.

The metrical system has just been adopted in Germany for the measurement of distances. The official papers have published the order with decrees that henceforth the kilometre shall replace the Prussian mile.

The additions to the Zoological Society's Gardens during the past week include a pair of Coatis (*Nasua nasica*) from South America, presented by Mr. W. P. Chambers; an Egyptian Fox (*Canis niloticus*) from Port Said, presented by Mr. J. T. Keane; a Bonnet Monkey (*Macacus radiatus*) from India, presented by Mr. R. Wilkinson; a Great Kangaroo (*Macropus giganteus*), born in the Gardens; five Branched Sea Horses (*Hippocampus ramulosus*) from the coast of France, purchased; a Capybara (*Hydrochœrus capybara*) from Rio Negro.

SCIENTIFIC SERIALS

In the *Journal of Botany* for January, there is no paper of special general interest, the illustration being that of a new British moss *Tortula inclinata*. Mr. J. G. Baker describes a number of new or little known capsular gamophyllous Liliaceæ; and Mr. F. E. Kitchener gives an "elementary proof of the rule for detecting spiral arrangement." The first article in the February No. is an illustration of how much yet remains to be done in completing the British flora, being a description with a plate of a British Dock, *Rumex maximus*, discovered by the Hon. J. L. Warren in the neighbourhood of Lewes, where it was recorded many years since, but not having been observed in the meantime, had been generally treated as an error. There is no other paper bearing specially on British Botany, but a very useful account of the Esparto-grass of commerce, by Mr. J. R. Jackson.

Astronomische Nachrichten, No. 1972. The elements of Henry's comet, 1873, by E. Weiss and Aug. Zielinsky, the following elements are given :—

	Weiss. Berlin Time.	Zielinsky. Paris Time.
T =	Oct. 1·80022	Oct. 1·765792
Π =	50° 28′ 18″·5	50° 18′ 42″·96
☊ =	176° 43′ 14″	176° 43′ 21″·88
i =	121° 28′ 58″·8	121° 27′ 48″·19
log q =	9·585297	9·586641

A list of fifteen new nebulæ is given, which M. Stephan observed at Marseilles.

Poggendorff's Annalen der Physik und Chemie, No. 10, 1873.—We may first notice, in this number, some observations relating to phenomena of light.—M. Behrens contributes a paper on the production of coloured light through elective reflection. The reflected and transmitted light of opal and other bodies was examined with a micro-spectroscope; and it is shown that certain substances may have colour without absorbing light, and that the two spectra (from reflection and transmission, respectively) are exactly complementary of each other. This, he says, occurs more frequently than one might suppose.—Dr. Nöggerrath draws attention to the production of light in grinding of hard stones, as witnessed in the agate-works at Oberstein and Idar. In the case of all hard stones (which the workmen press with their hands against large grindstones revolving thrice in a second), a strong red light appears between the object and the grindstone, with a red halo and emission of sparks. Transparent stones, however, are lit up throughout with a beautiful yellowish-red light, like that of glowing iron, so that it seems as if the workman must burn his hands (though the rise of temperature was not above 10° or 12° R.). The author invites research in this direction, for which the works named present good opportunity.—The concluding portion of M. von Bezold's paper on the law of colour mixture and the physiological primary colours, is given; the author is led to some valuable deductions which we cannot here stop to particularise.—M. Valerius, in a note on binocular, as compared with monocular, vision, comes to the conclusion that the proportion of brightness of an object, looked at successively with both eyes, and with one, is nearly independent of the absolute amount of illumination: and with ordinary candle or gas flame, does not exceed 1·15. He afterwards found that his left eye was less sensitive than the right; had he used the latter, the proportion in question would be somewhat less. The measurements were made with Foucault's photometer.—M. Kundt contributes a paper on the vibration of rectangular, and especially of square, *air plates;* meaning, by an air plate, a thin layer of air enclosed between two solid plane plates applied to each other (it may be either in communication with the external air, or closed all round). He makes the vibration-forms visible by means of cork powder; and the present communication chiefly shows that the vibration-numbers observed in the entirely-closed air plates agree with those deduced from theory, to less than 1 per cent.—Dr. Hübener gives an account of researches on transpiration of salt solutions through capillary tubes. The velocity of outflow is found to be inversely as the equivalent weights; which may be explained (the author thinks) by the fact, that in compounds with high equivalent weight the molecules are larger than in those with low. If, then, equal weights of two salts of different equivalent weight be dissolved in a liquid, there will be present in the solution of the heavier salt larger but fewer molecules than in the other solution. Hence, in the solution of the first salt, the molecular surface in contact with the solvent will be less than in the second liquid; and the internal friction will be less; thus (other conditions equal), there will be greater mobility.—A paper by Dr. Dibbits discusses, at some length, the dissociation of ammonium salts in aqueous solution; the results detailed being both qualitative and quantitative.—M. Rammelsberg communicates a second note on natural compounds of tantalum and niobium; and Dr. Bender describes an ingenious method of determining the time of vibration of a material pendulum. The remaining matter does not specially call for notice.

SOCIETIES AND ACADEMIES

Royal Society, Feb. 5,—"On the Anatomy and Habits of the genus *Phronima* (Lattr.)." By Dr. John Denis Macdonald, F.R.S., Staff Surgeon R.N., Assistant Professor of Naval Hygiene, Netley Medical School.

Of all groups of Crustacea the Amphipoda would appear to exhibit the widest range, in the modification of their parts or organs, without obliterating the delicate lines of natural affinity running through them as a whole. This is well exemplified in the interesting paper of Dr. R. Willemoes-Suhm, naturalist to the *Challenger* Exploring Expedition, "On a new Genus of Amphipod Crustaceans" founded by him, and named *Thaumops*. This genus, although exhibiting many characters in common with *Phronima*, presents some striking points of difference traceable in the external jaw-feet, caudal appendages, the position of the generative bone, and certain particulars in its external anatomy.

During the exploratory voyage of H.M.S. *Herald*, in the S.W. Pacific, numerous species which I have always been in the habit of referring to the genus *Phronima*, were taken in the towing-net; and I might remark that the assumed parasitic habit of these creatures was never, at least, a prominent fact to me, they were so often taken either perfectly free, or tenanting a nidamental case. Those who, like Dr. Suhm, are acquainted with deep-sea dredging, are usually cautious how they refer the doubtful products to their proper habitat; whether it be the bottom that has been reached, or some zone of the watery space above. Indeed it is quite possible for the narrow area of the tallow-arming of the deep-sea lead to include fortuitously, and carry down *Phronima* or any other little crustacean naturally living near the surface; and contact with the bottom would finally press it into the tallow, so as to mislead the observer as to its true habitat. Conversely, in bringing up the dredge from a given depth, it may finally carry with it any more superficial objects casually lying in the track which it takes.

The author then describes a species of *Phronima* captured in lat. 30° 16′ S., long. 176° 27′ W.

The evidence of Dr. Willemoes-Suhm supports my own experience that there is no metamorphosis in this group; and as it is very probable that the history of the development of *Thaumops* would resemble that of *Phronima*, the following observations may be of some importance, as carrying the process a little further than it has perhaps yet been traced by him:—

In lat. 21° 0′ S. and long. 17° 45′ W. off the island of Ono, Fiji group, apparently the same species of *Phronima* as that above referred to was taken in the towing-net, but with the addition of a numerous progeny of young in a large gelatinous but tough nidamental case. This interesting nest was shaped like a barrel, but with both ends open, and the external surface was somewhat tuberculated and uneven. The wall of the tube presented numerous round and puckered openings, observing no very definite arrangement, but through which entering currents were observed to pass. These openings in general pierced the tuberculations, though not invariably.

An external membrane, with an internal lining, was distinctly visible, both seeming to be continuous at the rims of the tube. The space between these layers was filled up with a pulpy substance, in which scattered nucleiform bodies were detected with a higher power of the microscope.

In a subsequent commission on the North-American and West-Indian Station in H.M.S. *Icarus*, I have frequently captured "*Phronima* in its bay," as my messmates would say. In order to bring the swimmerets into full play, the animal protrudes its body tail foremost from the case, only calling into use the fine tips of the third and fourth pairs of thoracic limbs to hold fast its charge. When it fully retires into the case, the claws of the two posterior pairs of legs are pressed backwards against the lining membrane, so as still more effectually to secure its hold on the approach of danger.

Royal Society, Feb. 12.—"Note on the Synthesis of Formic Aldehyde," by Sir B. C. Brodie, Bart., F.R.S.

In a former note I communicated to the society the result of an experiment in which a mixture of equal (or nearly equal) volumes of hydrogen and carbonic oxide had been submitted, in the induction-tube, to the electric action. My expectation in making the experiment had been that the synthesis of formic aldehyde would be thus effected according to the equation $CO + H_2 = COH_2$. The only permanent gas, however, other than the gases originally present in the induction-tube, which appeared in the result of the experiment was marsh-gas. When a mixture of hydrogen and carbonic acid gas were similarly operated upon, the same hydrocarbon, together with carbonic oxide, was formed. I have now, however, succeeded, by a modification in the conditions of the latter experiment, in attaining the object which I originally had in view. Evidence of this is afforded by the following analysis:—The gas analysed was the result of submitting to the electric action equal volumes of hydrogen and carbonic acid. After removal from the gas of carbonic acid and carbonic oxide, and also of a trace of oxygen, 191·2 volumes of gas remained, in which were found at the conclusion of the analysis 2·6 volumes of nitrogen. Deducting this amount of nitrogen, 188·6 volumes of gas remain, containing the residual hydrogen in the gas, together with any gases besides carbonic oxide formed in the experiment. This gas was analysed by the addition of oxygen and subsequent detonation by the electric spark, the absorption of the carbonic acid by potash, and the removal of the oxygen over by pyrogallate of potash. The results of the analysis entirely concur with the assumption that the 188·6 volumes of gas were constituted of hydrogen, marsh-gas, and formic aldehyde in the proportions given below.

Hydrogen	183·2
Marsh-gas	0·2
Formic aldehyde	5·2
	188·6

The composition of 100 volumes of the gas being,

Hydrogen	97·14
Marsh-gas	0·10
Formic aldehyde	2·76
	100·00

Another experiment was attended with similar results, only that the proportion of marsh-gas was somewhat greater.

The result of this experiment may be considered to be given in the equation $CO_2 + 2H_2 = COH_2 + H_2O$. I have reason to believe that formic aldehyde is also formed in the reaction of hydrogen and carbonic oxide; and that the marsh-gas found (in both experiments) results from the decomposition of this substance, possibly according to the equation $2COH_2 = CO_2 + CH_4$. I do not now dwell upon this subject, as it is my intention very speedily to lay before the Society, together with other matters, the details of the various experiments which I have made in reference to it.

Geological Society Feb. 4.—His Grace the Duke of Argyll, K.T., F.R.S., president, in the chair.—The following communications were read:—"The Physical History of the Valley of the Rhine," by Prof. A. C. Ramsay, LL.D., V.P.R.S., vice-president. The author first described the general physical characters of the valley of the Rhine, and discussed some of the hypotheses which have been put forward to explain them. His own opinion was that during portions of the Miocene epoch the drainage through the great valley between the Schwarzwald and the Vosges ran from the Devonian hills north of Mainz into the area now occupied by the Miocene rocks of Switzerland. Then after the physical disturbances which closed the Miocene epoch in these regions the direction of the drainage was reversed, so that after passing through the hill-country between the lake of Constance and Basel, the river flowed along an elevated plain formed of Miocene deposits, the remains of which still exist at the sides of the valley between Basel and Mainz. At the same time the Rhine flowed in a minor valley through the upland country formed of Devonian rocks, which now constitute the Taunus, the Hundsruck, and the highland lying towards Bonn, and by the ordinary erosive action of the great river the gorge was gradually formed and deepened to its present level. In proportion as the gorge deepened, the marly flat Miocene strata of the area between Mainz and Basel were also in great part worn away, leaving the existing plain, which presents a deceptive appearance of having once been occupied by a great lake.—"On the Correspondence between some Areas of Apparent Upheaval and the Thickening of Subjacent Beds," by W. Topley, Geological Survey of England. The author referred to many instances in which beds have unequal development, being much thicker in some places than in others; and the main object of his paper was to show that such thickening and thinning of beds has an important effect in producing the apparent dip of overlying beds. The thinning of any one bed may have an appreciable effect in producing or increasing its own apparent dip; but where a whole series of beds thin constantly in one direction, the amount of the dip of one of the higher beds, due to the *sum of the thinnings of the underlying beds*, is often very considerable. It is generally supposed that the dip of any bed is due to great movements of the earth's crust; from the facts mentioned the author argued that our inferences as to such movements will vary according to the beds which happen to be exposed at the surface. It is evident, from the faults intersecting strata, that upheavals and disturbances have taken place; but unless we assume every bed to have been deposited on a perfectly horizontal plane, we cannot infer the amount of such upheaval from the present position of the bed. In all cases we must take into account the actual or possible thinning of underlying beds. The beds which support geological basins frequently thin towards the centres of those basins, thus producing, wholly or in part, the basined form of the strata. It was, however, shown that the beds of the basins themselves frequently thicken towards the centre of the basins.

Anthropological Institute, Feb. 10.—Prof. Busk, F.R.S., president, in the chair.—The second part of the paper "Explorations amongst ancient Burial Grounds, chiefly on the sea-coast valleys of Peru," was read by the author, Mr. Consul Thomas J. Hutchinson. The paper treated of the burial grounds from Lima northwards, as did the former part of the paper on those from Arica to Lima. Mr. Hutchinson described a burial place with the Aymara name of Parárá on the Oroya railroad at a station called Chosica, and at an elevation of only 2,750 feet above the level of the sea, and so named from its grinding stones used for bruising corn, numbers of which lie amongst the cenotaphs. Those were said by Prof. Forbes to be used for cooking purposes, because the Aymaras are stated to have occupied a part of Peru of which the minimum elevation is 10,000 ft., and therefore where the boiling of water is a difficult matter to accomplish. The flattened and elongated skulls mentioned by Dr. Tschudi and Prof. Forbes were touched upon—an illustration of one of these from an elevation of 10,000 ft. above the sea being given. Mr. Hutchinson recommended a further and more extensive exploration of the mounds and Huacas in Peru to illustrate the rich treasures of archæology with which that country abounds.—A joint paper by Mr. Tyrwhitt Drake and Mr. A. W. Franks was read, on skulls and implements from Palestine.

Photographic Society, Feb. 10.—James Glaisher, F.R.S., president, in the chair.—A special general meeting was held to decide whether two new laws, previously proposed, should be adopted, or whether the Council's amendment to appoint a committee to revise the laws generally be accepted. The Council's amendment was lost. The anniversary meeting of the Society was held afterwards, when the balance-sheet, showing an improved financial position, and the report of the Council, were read and adopted. The President and Council, interpreting the rejection of their amendment as a vote of want of confidence, then tendered their resignations, which were accepted.

MANCHESTER

Literary and Philosophical Society, Jan. 19.—Microscopical and Natural History Section.—Mr. Joseph Baxendell, F.R.A.S, vice-president of the Section, in the chair.—Mr. Joseph Sidebotham, F.R.A.S., read a paper no "The similarity of certain Crystallised substances to Vegetable forms." The author called attention to the formation of verdegris on insect pins, in old Entomological collections. This substance makes its appearance where the pins pass through the thorax of the insects, and in length of time grows into a considerable mass of flocculent matter, of a brilliant green colour, and often breaks up the insects and also destroys the pins. It consists mainly of acetate or formiate of copper in combination with fatty or oily matter. On examination of various specimens under the microscope, they were found to present a great variety of forms, filamentous and ribbon-like structure, often resembling various

fungi, in some cases so nearly, that it was difficult to believe that the fibres and fruit-like forms are not really organic bodies. The author expressed his opinion that these bodies were simply crystals, modified in their formation by the oil contained in the insects, with which the crystals are in some way combined. Some of the specimens exhibited were taken from insects collected twenty-five years ago.

LIVERPOOL

Geological Society, Feb. 12.—Mr. T. Mellard Reade, F.G.S. read a paper containing a series of novel investigations on the action of tides on the sea-bottom. Applying a formula used by civil engineers, the result of practical observation in tidal estuaries, to the observed currents at the surface at various points in the St. George's and English Channels, it was proved, by comparison with experiments instituted for ascertaining the moving powers of running water on materials of various specific gravity and bulk, that, conditions being otherwise favourable, tidal currents were capable of destructive erosive action on the sea-bottom. Mr. Reade then entered elaborately into the phenomena of the tides in the Irish Sea, in the English Channel, and surrounding seas, using Captain Beechey's admirable observations for this purpose. Mr. Reade infers from a consideration of a variety of circumstances that the materials of the Irish Sea bottom are principally composed of re-arranged glacial drift, either eroded off the bottom or off the coast by the sea itself, or poured into it by the many rivers in the north-west of England, south of Scotland, and west of Ireland, draining vast basins mostly covered by glacial clays and sands. These materials, notwithstanding the oscillatory character of the tidal streams, have in the main a slow, progressive motion down channel, and out as far into the Atlantic as the little Sole Banks. Clear cases of the erosive action of the water on the bottom were then given. It was shown that there are pits or gullies excavated in the bottom in both the English and Irish channels, and that these depressions have generally their major axes conformable in direction with the set of the stream tide; and that the contour lines of the bottom approximately follow the same direction. The most remarkable of these excavations is the North Channel Gulley, off the coast of Wigtonshire, twenty miles long, one mile wide, and from 400 ft. to 600 ft. deeper than the surrounding bottom, and which the strong tide existing there has either partially or wholly excavated, and now keeps open. In conclusion, Mr. Reade expressed his conviction that the diurnal and semi-diurnal movement of the tides, acting down to the profoundest depths of the ocean, accounts for the preponderance of life in it over that exhibited by the fauna of the Mediterranean.

EDINBURGH

Royal Society, Feb. 16.—Sir William Thomson, president, in the chair.—The president read obituary notices of deceased Fellows of the Society.—The following communications were read:—On the Kinetic Theory of the Dissipation of Energy, by Sir W. Thomson.—On the Electric Conductivity of Iron at a Low Red Heat, by Prof. Tait.—On the Stresses due to Compound Strains, by Prof. C. Niven, communicated by Prof. Tait.

GLASGOW

Geological Society, Jan. 15.—Mr. E. A. Wünsch, vice-president, in the chair.—Mr. R. L. Jack, of H.M. Geological Survey, read a paper on a Boulder-clay, with broken shells, in the lower valley of the River Endrick, near Lochlomond, and its relation to certain other glacial deposits in the same neighbourhood. The author stated that the elevation of Lochlomond above the sea is so trifling that there is no difficulty in classing it with the sea-lochs that indent the western Highlands. A depression of 20 feet, or the removal of the superficial deposits traversed by its short outlet, the Leven, on its way to the Clyde, would restore it to its former condition. He then called attention to a deposit which he had observed in the course of his work on the geological survey near the south-eastern angle of Lochlomond, and whose relation to the already-known members of the glacial series seemed to deserve particular attention. The deposit is a true typical till, in every respect similar to the old boulder-clay or till of the Lowlands of Scotland. In a matrix of stiff unstratified clay, brown in colour, like the subjacent Old Red sandstone rock, are scattered stones of various sizes, blunted, smoothed, and marked with striations in all directions, but most frequently in the direction of their longer axis. It presents, however, one remarkable peculiarity that distinguishes it from the common till—it contains worn and broken fragments of marine shells. Though he had not found any clear instance of an older deposit below this shelly till, he believed its place was above the old boulder-clay, and that it was also the product of land-ice. He believed the till to be the product of land-ice—the *moraine profonde* of a large glacier which filled up the lake, covered the islands, and climbed the rising ground between the Leven and the Endrick to the height of at least 320 feet. This glacier, in all probability, existed during the latter portion of the period which preceded the "great submergence" of the land.—Mr. John Young read a paper on the occurrence of a bed of highly indurated Sandstone, with water-worn quartzite pebbles, interstratified with the trap of the Campsie Hills. The bed is probably of lower carboniferous age, and indicates one of those periods of repose between the great outbursts of igneous rock matter of which the Campsie Fells are principally built up.

PARIS

Academy of Sciences, Feb. 9—M. Bertrand in the chair.—The following papers were read:—On *Balistique intérieure*, by General Morin. This was a paper on the various forces acting on a projectile whilst still in the bore of a gun.—On the devitrification of glass, by M. Eug. Peligot. The author decides that, contrary to the received opinion that this effect is due merely to a crystallisation of the glass, it is due to the formation of a definite silicate having a formula corresponding to that of a pyroxene.—On the action of water on lead, by M. Balard.—New clinical and experimental researches on the movements and repose of the heart, and on the mechanism of the passage of the blood through its cavities when in the normal state, by M. Bouillaud.—On the preservation of vines threatened by *Phylloxera*, by M. de la Vergne.—On the problem of three bodies, by M. E. Mathieu.—On the resistance of glass tubes to rupture, by M. L. Cailletet. The author finds that a tube stands pressure from the outside better than from the inside. The pressures, however, which a tube can stand from the inside are very great. One of 9 mm. internal diameter and 1 mm. thickness, containing 6·9 c.c., was submitted to an outside pressure of 460 atmospheres, without injury, and subsequently to an internal pressure of 104 atmospheres, when it burst.—On the use of a double refracting prism for determining the axes of ellipses, by M. Jannetaz.—On some new bands produced in the absorption spectrum of chlorophyll by reagents containing sulphur, by M. J. Chautard.—On a new process for preserving wood, by M. Hatzfeld.—On the hardness and density of carbon obtained from pure sugar, by M. F. Monier.—On the flight of birds, by M. E. Bertin.—On an electric fire-alarm, by MM. A. Joly, and P. Barbier.—On the measurement of heat, by M. G. West.—On a case of monstrosity, &c., by M. Claudot.—Theorems concerning algebraic equations, by M. F. Lucas.—On the impossibility of certain double equations, by M. A. Genocchi.—On the conditions necessary for a conic with a curve of any order to have a contact of the fifth order, by M. Painvin.—On the chemical characteristics of the uredo of maize, &c., by M. Hartsen.—On the consecutive effects of the removal of the mammæ in certain animals, by M. de Sinéty.

THE ROTHAMSTED AGRICULTURAL INVESTIGATIONS

IT has become a trite remark, that while both the progress and teaching of Science are fostered in most educated countries by the care of the State, they mainly depend in our own country on the exertions of private individuals; this fact is perhaps, however, more strikingly seen in the case of agriculture than in any other instance. The traveller in Germany will find scattered over the country, some forty Experimental Stations and Agricultural Academies, establishments which are devoted to the investigation and teaching of scientific agriculture and are maintained by their respective States. The German farmer has thus the means of becoming acquainted with the true science of his business, and provision is at the same time made for the investigation of the various problems with which his work abounds. In England the state of things is, alas, wholly different. We have just one college—that at Cirencester, devoted to the teaching of scientific agriculture, and one Experimental Station—that at Rothamsted. There is indeed some experimental work done by local Farmers' Clubs, but this is generally only with the object of comparing the effects of the various manures that are in the market, and with no scientific aim or result. Yet England preeminently needs the help of Science to direct economically her vast system of agriculture. The art of agriculture is here in a higher state of development than on the continent. More capital is here invested in the land; more attention has been paid to tillage, to artificial manures, and to the breeding and feeding of stock. The British farmer succeeds because he is a practical man, and has good common sense, and the enterprising spirit of his race; what might he not do if he thoroughly understood the principles which underlie his art?

If we have but one agricultural station in England we have at least reason to be proud of it. The work done at Mr. Lawes' estate at Rothamsted is not to be equalled by that of any of the foreign stations; indeed, in several departments of investigation it might safely challenge a comparison with their united efforts. This excellence has arisen from the systematic and thorough manner in which the subjects taken up have been treated. We cannot better illustrate this than by referring to the last contribution from Rothamsted, a report by Messrs. Lawes and Gilbert on the growth of barley.*

In one of the experimental fields barley has been grown for twenty years, and the experiment is still progressing. The field is divided into plots of about one-fifth of an acre; some of these have never received any manure during the twenty years; the others receive some one or more of the food constituents which barley requires. Thus one is manured with phosphates, a second with alkalies, a third with ammonia, a fourth with ammonia and phosphates, a fifth with ammonia, phosphates, and alkalies, &c. The same manures are always applied each year to the same plot. At harvest the crops are carefully weighed, and are then analysed in the laboratory under the superintendence of Dr. Gilbert, the amount of dry matter, ash, and nitrogen being determined. The advantages of this systematic mode of experimenting are very great. Carried on in the same manner for so many years, these experiments answer questions relating to the exhaustion of soil, to the permanent effect of manures, to the effect of season upon the produce. With the aid of the laboratory investigations they teach us what proportion of the various ingredients supplied in the manure is recovered in the crop, and how the composition of the plant is affected by the various conditions of the soil. In conjunction with analyses of the soil and of the drainage water, we learn what becomes of the manures applied, how deeply they have penetrated into the soil, what is the loss suffered through drainage, &c. A single field experiment thus thoroughly and patiently carried out touches half the domain of agricultural chemistry, and supplies information of the most solid and valuable kind.

The value of every trustworthy investigation is increased as others are completed which compare with it; the work at Rothamsted thus derives an additional value from its extent. During the last thirty years Messrs. Lawes and Gilbert have investigated in the manner described all the principal farm crops, experimenting both on each singly, and also on their behaviour when grown in rotation. As the results are gradually published, and we are able to compare the behaviour of different crops grown on the same soil, with the same manures, and in the same seasons, the special characteristics of each crop become plainly shown by contrast with its fellows, and we gradually learn the part which each is fitted to play in a scientific system of agriculture.

Nitrogenous manures are of primary importance if luxuriant cereal crops are to be raised, the natural supply of combined nitrogen from the atmosphere being very small, and the crops in question having little power for assimilating the forms of nitrogen chiefly present in the soil. Nitrogenous manures are, moreover, as every farmer knows, very expensive, and it is a matter of great importance to employ them in the most economical manner. Messrs. Lawes and Gilbert, knowing the composition of the manure that has gone on to their fields, and the composition of the crops that have been carted off, can tell exactly what proportion of the nitrogen applied has been assimilated by the plant. They find, on an average of twenty years, that wheat assimilates about 45 per cent. of the nitrogen in a spring dressing of nitrate of sodium, and about 33 per cent. in the case of an autumn dressing of sulphate of ammonium, and only $14\frac{1}{2}$ per cent. of the nitrogen supplied by farmyard manure. With barley, the proportion assimilated is rather greater, being 49 per cent. for a spring dressing of ammonium salts. The question as to what becomes of the large proportion of unused nitrogen is clearly of the highest importance. Analyses of the soils, and of the drainage water, throw much light on the subject. The soils of the wheat field have been analysed down to a depth of 27 inches. A considerable part of the missing nitrogen is found to be actually present in the soil, but since it has scarcely any effect on the crops, it is apparently in some state of combination unsuitable for the plant's use. A still larger portion of the nitro-

* "Report of Experiments on the Growth of Barley for twenty years in succession on the same land," by J. B. Lawes, F.R.S., F.C.S., and J. H. Gilbert, Ph.D., F.R.S., F.C.S.—*Journal of the Royal Agricultural Society*, 1873, 89 and 275.

gen is, however, not to be found in the soil, but the examination of the drainage waters from the different plots exhibits so large a content of nitrates, that calculation leads to the belief that in the case of ammonium salts and nitrate of sodium the loss of nitrogen chiefly takes place in this manner. Chemists knowing that ammonia is readily absorbed and firmly held by soil, had never anticipated that so considerable a loss might occur by drainage. It plainly appears, however, from these results, that ammonia when applied to the soil is quickly converted into nitric acid, and in heavy rains may be easily washed out. During autumn and winter there is little evaporation from the soil, and no consumption of water by a growing crop; as soon therefore as the surface soil is saturated most of the subsequent rain-fall will pass into the subsoil, or find its exit through the drains. The authors calculate that if the drainage water contains 1 part of nitrogen in 100,000, and many of the waters analysed were much richer, there will be a loss of 2·26ths of nitrogen equal to about 23 lbs. of guano for every inch of rain that passes beyond the reach of the roots. It is evident, among other conclusions from these important facts, that ammonia should only be applied to the land in the spring, when the crop is able to make immediate use of it. It may also be found that on gravelly and sandy soils, which have little power of holding water, organic forms of nitrogen, as rape cake and farm-yard manure, may be more certain in their effects than ammonia or nitrates. The organic manures being only slowly rendered soluble in the soil, can suffer comparatively little loss from sudden rain. The subject of the economic application of nitrogen is being further investigated at Rothamsted.

We have no space to do more than allude to the researches which have been conducted at Rothamsted in the department of animal chemistry: the experiments on the fattening of stock, and on the composition of the carcase produced, have been equally important in their results with those field experiments we have referred to. Of the indebtedness of Science to Mr. Lawes' unique and costly experiments we need not speak, the facts are so plain that they speak for themselves. Nor need we state the moral. The addition to the national wealth which has accrued from the discoveries made by Mr. Lawes is already enormous. It must be borne in mind that this benefit has arisen from *accidental* researches, for Mr. Lawes was not compelled to take them up, nor is he bound to continue them. Now if such work is not national work, The Royal Observatory ought to be shut up to-morrow, for the work done there is not one jot or tittle more important.

DR. LIVINGSTONE

THE telegram, dated at Aden on the 23rd of this month, announces that Lieut. Murphy is bringing the body of Dr. Livingstone down to Zanzibar, while Lieut. Cameron has passed onwards to Ujiji to recover Dr. Livingstone's papers and to continue his work. The story of those faithful negroes having carried the body of their beloved chief over hundreds of miles is one of the most romantic in history, and is a fitting close to the noble life of the great explorer. Dean Stanley, we are informed, has proposed that the remains of Livingstone shall find a last resting-place in Westminster Abbey. Yesterday (the 25th) was the last day on which instructions could be sent out by telegram touching the disposal of the body. We cannot believe that the necessary orders have not been despatched; for the wishes of the country are well known, and have been sufficiently expressed. With the body will arrive all Livingstone's faithful followers, who were engaged on the understanding that they were to receive a certain fixed monthly payment. There were Chumah and the two or three other men who had been with him since 1865. There were Jacob Wainwright and the other Nassick boys, and the men sent up to Unyanyembe in the summer of 1872; and there were the men engaged in the interior by Dr. Livingstone himself. A sum of about 1,000*l.* will be required to pay off these loyal and faithful servants of Her Majesty's Consul. Yesterday was the last day on which an order for the payment could be sent out. Has this been done? The people of England have a right to an answer, and an immediate answer, for if the Government hesitates, the country will never allow this disgrace to come upon it.

As soon as the full details arrive by the next mail, it will be fitting that we should give our readers a memoir of the illustrious martyr to Science who has passed away. But now we desire to know—and all England will join with us in the inquiry—whether orders were sent out by telegram on the 25th, respecting the disposal of Dr. Livingstone's body, and the payment of his followers, the devoted servants of Her Majesty's Consul?

Lieut. Cameron, in conducting the search expedition, has suffered terribly from fever and ophthalmia, and has been obliged to incur heavy expenses. But he has displayed the best qualities of an explorer. He is a good manager of natives, an excellent walker, an accurate astronomical observer, a linguist, and a man of indomitable perseverance. He is now pressing forward on a perilous and important duty, and we trust he will carry with him the generous sympathy of the Geographical Society, and of the public generally.

POST-TERTIARY GEOLOGY

The Great Ice-Age and its relation to the Antiquity of Man. By James Geikie. (W. Isbister and Co. 1874.)

I.

EVERY field-geologist, who works in northern latitudes, soon comes to know what is meant by Drift. In his attempts to trace the superposition and run across the country of the solid rocks, he is always sooner or later brought up by coming across masses of stony clay, gravel, and sand, which bury them to greater or less depths, and more or less completely hide them from view. These superficial accumulations lie indifferently on all members of the bedded formations; they occur now in detached patches, and now spread like a pall over vast tracts of country.

In the latter case it is clear that they would soon make their presence felt by the way in which they effectually mask the geological structure of the ground they cover; it was impossible, therefore, that they could be for long ignored altogether, but they seem for a time to have been looked upon as something very inferior in interest and importance to the older and more regular formations, in some

cases, perhaps, as little more than troublesome hindrances to the making of a good geological map. Thus it came about that deposits of this class were lumped together under the comprehensive title of Diluvium or Northern Drift: and that, in the few cases where any geologist thought them worthy of more than a simple recognition, the explanations offered of their origin were crude and unsatisfactory. Some of these explanations we may just glance at. In the days when evolution and continuity were doctrines yet undreamed of, it was imagined that between any two consecutive geological epochs there intervened a period of chaotic turmoil, one result of which was, that a clean sweep was made of the life of the epoch that had just closed, and the ground prepared for the introduction of the life of that which was to follow. Supposing this to have been the general course of past events, some referred diluvial accumulations to the series of convulsions which came in like a great gulf between the age of man and the last of geological eras. It could not be reasonably objected to such an hypothesis that it called to its aid agencies the like of which we had never seen, and the like of which, as far as our knowledge of the economy of nature went, it was most improbable had ever been in operation; there was the ready answer, that during periods which were essentially abnormal, anything was possible. This made such explanations easy to frame and easy to uphold, and they commended themselves readily to the indolence of mind and impatience of accurate thought from which few of us are altogether free. The same may be said of the notion suggested by, but we cannot say based upon, the phenomena of the great ocean wave of earthquakes, "that somehow and somewhere in the far north a series of gigantic waves was mysteriously propagated," which "were supposed to have precipitated themselves madly on over mountain and valley alike, carrying along with them a mighty burden of rocks, stones, and rubbish," and that by this means the piles of diluvium had been heaped up. Again, the name diluvium was founded on the idea that its deposits were the relics of Noah's flood; and the notion that we had in them a proof of the accuracy of the Biblical record was so very welcome, that it was accepted and stuck to in spite of the absence of evidence in its favour, and so contributed, perhaps as much as anything else, to postpone the true solution of the problem.

But by degrees light began to dawn on the subject. Playfair had attempted to turn the attention of geologists to the proper quarter, when he suggested that the most powerful agents which Nature employs for the moving of rocks are the glaciers; but his hint lay for a while unheeded. In 1837, Agassiz arrived at the conclusion that the glaciers of the Alps had been formerly far larger than at present. He had studied the smoothed and furrowed surfaces which occur everywhere below glaciers, and had found that the rocks displayed markings exactly identical with these far beyond the range of the present ice. He explained his views to Buckland, who then saw the meaning of certain surface features which he had observed, but had not previously understood, in the British Islands. The two geologists visited Scotland together in 1840; found over the length and breadth of the land scorings and polishings which ice—and, as far as their knowledge went, nothing but ice—could have made, and came to the conclusion that the whole country had been once swathed in one widespread ice-covering. About the same time Sir Charles Lyell attributed the formation of portions of the Scotch drift to the action of land-ice.

The right clue was now found, and it only remained for others to follow it up. A great step was made by Prof. Ramsay when, some ten years later, he deciphered the story written on the Drift-beds of North Wales, and determined the broad succession of physical changes that had led to their formation. He pointed out that there had been two periods of cold, the first of intense severity, and the second less rigorous, and that between the two there came a milder interval, during which depression brought the sea up the flanks of the mountains to a height of 2,300 feet above its present level.

Still however the importance of the Drift was far from being fully recognised. For many years no notice whatever was taken of it on the maps of the Government Survey; and when at last it met with a tardy recognition, Drift was still for a while Drift "and it was nothing more," a something agriculturally important and therefore not to be passed over by the economic geologist, but hardly a great formation with a story to tell as long, as varied, and as interesting, as any that geology had hitherto revealed to us. It is significant that ever so eminent a pioneer as Prof. Ramsay did not deem these deposits worthy of more than incidental notice in his otherwise exhaustive Memoir on the Geology of North Wales. The Drift in fact was somewhat on the position of a *nouveau riche*, who is trying to work his way into "society," and it had up-hill work before it was admitted into the exclusive circle of the old respectable formations.

But its turn came at last, and amid the band of geologists, who have helped in the work of securing for it the attention to which it is fairly entitled, the brothers Geikie occupy prominent places. The one gave us in 1863 his paper on the phenomena of the Glacial Drift of Scotland, in which he offered a masterly summary of all that was known on the subject up to the date of its publication, and settled for ever the claim of land-ice against ice-bergs to have been the agent that formed the Scotch Till; and now the other comes before us with the goodly volume, whose title stands at the head of this article, and which can be cordially recommended both to the geologist and the general reader. Its account of the labours and conclusions of previous workers is all but exhaustive, but it is far more than a mere *résumé*; a long practical acquaintance with Drift-deposits has enabled the author to add materially to our knowledge of the course of events that accompanied their formation, and in some cases has led him to demur to views hitherto all but universally accepted; and his own contributions and criticisms are as remarkable for the boldness of their originality as for the soundness of the reasoning by which they are upheld. At the same time the explanations are so full, and the method of handling so free from technicality, that with a moderate amount of attention the book may be understood, and its reasoning followed, by those who had previously little or no geological knowledge.

A large part of the work is taken up by a careful and detailed description of the Drift-beds of Scotland, which country the author has chosen as a typical area. A better selection could not have been made, for in no

country perhaps are these deposits so largely developed, and nowhere have they been so elaborately worked out as by the distinguished band of geologists who have made Scotch glacial formations a special study.

The first seven chapters are devoted to a description of the Till, the lowest member of the Scotch Drift; and an explanation of the line of reasoning that has led geologists to acquiesce almost unanimously in the opinion that it was formed on land beneath a sheet of ice, which, during a period of intense cold, overspread the whole country, and pushed its way far out over the shallow bed of the surrounding sea.

So far the author has only been repeating and enforcing the conclusions of his predecessors, but in chaps. 11—14 he enters on ground which is all but his own. It has been long known that layers of well-bedded sand and gravel occur in the heart of the Till, and between it and the older rocks. These deposits however are local and of small extent, or had been detected only in borings or underground workings, and had had comparatively little attention paid to them. Mr. J. Geikie has for the first time pointed out that in spite of their small development they are full of meaning; and that, when this meaning is realised, the fragmentary nature of their occurrence is only what is to be expected, and that the wonder is, not that there is so little of them left, but that any of them should have survived to tell the tale which he has so ably extracted from them. And the story they tell us is this. They are evidently the products of running water, alluvial or lacustrine deposits mostly; now former observers had realised in a vague sort of way that they were a proof of changes of climate, which permitted water to flow over what had been before an ice-bound waste, but we have now clearly brought before us that the abatements of the intense cold, which these beds indicate, were not local and temporary, but wide-spread and of long duration, and that they recurred several times during the period of the first great glaciation. Thus we are led to see that the first subdivision of the great ice-age was not one dreary unbroken lapse of Polar winter, but that it included mild intervals, when the ice shrank back, possibly disappeared altogether, when vegetation reappeared, and when herds of the great mammals returned from the southern retreats into which they had been driven during the most intense phases of the cold. And these facts enable us to realise more vividly the immense lapse of time represented by one division alone of the Glacial Formation. For if "we consider that the succession of changes happened not once only, but again and again, we cannot fail to have some faint appreciation of the lapse of time required for the accumulation of the Till and the Interglacial Deposits." Lastly Mr. Geikie has pointed out that these alternations of intense glaciation and comparative mildness are fully in accordance with the theory so ably expounded by Mr. Croll, that changes in climate are due to the combined effect of the Precession of the Equinoxes and variation in the eccentricity of the earth's orbit, a theory which he has lucidly expounded in chaps. 8—10.

We next come to certain deposits, the meaning of which seems first to have been clearly read by the author of the present work. At last the conditions which gave rise to the Till began to pass away and the climate to improve slowly, and the great glaciers ceased to be confluent; a depression of the land ensued so that the sea followed the retreating margin of the ice; but after a while, perhaps owing to an upward movement, the glaciers terminated on dry land. Mountain peaks now began to rise above the ice, and showered down on to its surface loads of *débris* torn from their exposed faces by frost. As the burden was shot over the ends of the glaciers, it gave rise to huge heaps of morainic rubbish, which at first fell into the sea, and afterwards, as the ice drew back, was shed upon the land. In this way were formed the subdivisions of the glacial formation which the author has distinguished as Boulder Clay and Morainic Rubbish. During this period the author believes that many of the erratic blocks, which form so conspicuous a feature among glacial deposits, were stranded from the ice-sheet as it drew back; and he gives good reasons for preferring this explanation to the older notion, which supposed these travellers to have been dropped from ice-bergs during the submergence which came a little later on.

As the climate gradually improved, the melting of the ice swelled the rivers and gave rise to mighty floods, which thundered down the narrow mountain glens, sweeping before them portions of the Till and Morainic rubbish, and, when they emerged on the open valleys of the lowlands, spread out the worn and rounded materials in broad sheets of gravel. One point here we must pause specially to call attention to. Geologists had long been aware of the disappearance of the great ice-sheet and of a gradual submergence of the land which followed it, but we now learn that the first of these events had made considerable progress, perhaps had been completed, before the second had fairly set in.

The first act of the drama we are looking at may be said to close here; the second opens with the commencement of the submergence just mentioned. The land began to sink and went down till the sea reached to some 1,200 feet, perhaps in some cases to nearly double that amount, above its present level; and as each of the previously formed Drifts, Till, Boulder Clay, Morainic Rubbish, and Gravel, was brought under the action of the waves, they sifted and sorted it, washing out the fine dirt, and rounding and reducing in size the pebbles; and in many cases the clean gravel and sand so formed were piled up along each successive coast line in mounds and long ridges, which still retain the distinctive outline originally impressed on them by wave- and tidal-action. These hummocky piles and ridges are known as Kames or Eskers. That many Kames owe their present shape in the main to the direct action of the sea alone there can scarcely be a doubt; we find them sometimes for instance enclosing hollows *without any outlet*, a little tarn or peat moss occupying in some cases the central depression, and in such a case they must have been piled up by shifting currents, for in no other way could the closed basin in the middle have been produced. But many so-called Kames are only the remnants of large sheets of gravel, the greater parts of which have been carried away by denudation. It would be better perhaps to restrict the term to those mounds which were piled up originally very much as they stand now. Even with this limitation, however, Kames are plentiful enough, and they are found in greatest abun-

dance at the spots where the currents tending to their formation must have prevailed as the land went down; in cols, then straits connecting opposite firths from which tides would flow in on either side; at the openings of mountain valleys, where the stream with its gravel burden was then met by the incoming tide; on low plateaus lying between what were then estuaries, over which opposing currents would sweep each high tide; and in other similar situations.

But were the Kames formed as the land sunk, or during its subsequent emergence? One would be inclined to say during the latter period, for any heaps piled up by the incoming sea would be liable to be swept away when they again became exposed to wave-action as the sea retreated. Nevertheless, Mr. Geikie—and he is supported by other observers in his opinion—holds that it was during the period of depression that kame-building went on, for the following reasons. The material of the Kames is, for the most part, fine and well rounded, and it is a very rare thing to find a large angular boulder in the heart of a Kame; hence it is believed that during the formation of the Kames the climate had so far mended that glaciers no longer existed, and that therefore there were no icebergs to strew the sea-bottom with travelled blocks. Erratics are, however, common perched on the outside of the Kames, and hence it is concluded that at some point in the period of the submergence cold again began to come on, that glaciers reappeared and gave rise to icebergs which bore away these blocks and dropped them where they are now found. That there was a return to cold conditions we know from other evidence, and with the exception of the difficulty just mentioned, which after all is not very serious, for the Kames we have may be only the relics of a body originally much more numerous, the explanation accords well enough with our knowledge of the facts. But the thought crosses the mind that it is not very often that we have an opportunity of seeing into a Kame, or rather, that we see the outside much oftener than the inside, and that this possibly may be the reason why erratics seem to be more plentiful in the one place than the other.

OUR BOOK SHELF

Mineralogische Mittheilungen, 4th Heft. (Vienna, 1873.)

THE present number of the *Mineralogische Mittheilungen* forms the 4th volume of the series, commenced in 1870. It is published under the auspices of the K. K. Geol. Reichsanstalt, and in connection with their quarterly Jahrbuch, but forms properly in itself an independent journal. It is probably the only periodical devoted exclusively to mineralogy, and thus already occupies an important place among German scientific serials. The list of papers which appear in this number will give a good idea of the position which the journal occupies:—Mineralogical observations in the Argentine Republic, by H. Stelzner (embracing—minerals occurring in the granite quartz masses of Cordoba; minerals associated with the granular limestone; also analyses and special description of Triplite, Jamesonite, Enargite, Linarite, &c.); eruptive rocks of Banat, Hungary, by Niedzwiedzki; crystallised magnesite from the Northern Alps, by J. Rumpf; mineral observations from the Bohemian Forest, by Helmhacker; brief notices of various minerals, Grunochite, an optically uni-axial diamond, native copper, Roselite, &c. The number opens with a short obituary notice of Naumann.

The Mittheilungen are under the charge of Prof. Tschermak, so well known through the scientific world for his many and valuable contributions to mineralogy and lithology.

Prof. Tschermak occupies the position of Director of the Royal Mineralogical Museum of Vienna, a collection which in beauty and completeness is not inferior to that of the British Museum, while it surpasses the latter in the arrangement of the objects exhibited, especially in reference to the good of the general public. The Museum has been much enriched within the last four months by the acquisition of a number of interesting things from the Vienna Exposition. The collections are opened two mornings in the week, for the benefit of the public, opportunities which are well made use of, while the Cabinet is accessible on every week-day to those who are there engaged in regular work. The results accomplished in the Mineralogical School thus formed in connection with Prof. Tschermak and Dr. Schrauf do a considerable part toward supporting the *Mineralogische Mittheilungen.*

The Geological Reichsanstalt, now under the direction of Franz Ritter von Hauer, has carried on its work for twenty-seven years. The results are not only of the greatest importance in developing the resources of the Empire itself, but, as the work engages the best talent, and is consequently carried on according to the highest standard of pure science, the yearly labours are adding vastly to the fund of geological knowledge, and helping to solve many of the difficult problems of the science. The building occupied by the Reichsanstalt contains the various working-rooms, and the extensive collections, complete naturally in all matters pertaining to Austrian Zoology. The immediate results of the survey are first made known in the Evening Sessions, which are held on the first and third Tuesday of each month from November to May. They are attended regularly by some thirty or forty of those interested in such subjects, and form a pleasant opportunity for those of common interests to meet together informally. The stranger is continually impressed with the active spirit, and especially with the community of feeling, among the scientific men of Vienna; the latter has undoubtedy great influence in giving the city the prominent position which it occupies among the different scientific centres.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Zoological Nomenclature

FROM time to time an idea is started that Zoology is breaking down under the weight of its synonymy. With entomologists I have frequently contended that so far from this being the case, there is, on the contrary, an almost marvellous agreement in the generic and specific names used, especially when we consider the extent of the bibliography and the vast number of the species. After reading in NATURE, vol. ix. p. 258, Mr. Wallace's review of Dr. Sharp's pamphlet, I bethought myself of comparing the two best known catalogues of European Coleoptera, viz., Schaum's, published at Berlin, in 1862, and De Marseul's, at Paris, in 1866. Perhaps the results of the examination of the first six families in the two works will suffice. It must be premised that Schaum's is strictly confined to European species, while De Marseul's embraces as well those of the "basin of the Mediterranean in Asia and Africa." As to the genera, in the Cicindelidæ there are two in each. In the Carabidæ, Schaum has 98 genera and de Marseul 118; of the latter four are not adopted by Schaum and the remainder are extra-European. In the Dytiscidæ Schaum has 15 genera, De Marseul 17. In the Gyrinidæ there are two genera in Schaum, and three in De Marseul, the third being

extra-European. Hydrophilidæ not having the same limitation in the two works, I take the Palpicorn families in which that group and the Sphæridiidæ are included. There are 22 genera in each catalogue, but Schaum and De Marseul each ignore a genus adopted by the other, and a third name, Cyllidium, is preferred by the French author to the earlier one of Chætarthria. As to the species, seeing that Schaum has about 1,580 in the families mentioned above, and De Marseul 2,640, it would not be easy to compare them in a definite form; but taking Cicindela, the second genus of the two catalogues, the first having only one species, which is, I conceive, a fair example of the others, if indeed it has not had more than its share of varieties elevated to the rank of species, we find the 26 species in Schaum identical in names with the same species in De Marseul, except two varieties or species, and a synonym given with a ? by Schaum, which is the right name according to De Marseul.

I would venture to suggest that the synonyms which look so formidable to some of our friends, are principally due to the writers of local faunas, or in some cases to specialists, and that such names have, as a rule, never been adopted, and practically offer no hindrance whatever to the naturalist. A species may be described by an author who is ignorant that it has been previously described, but this is an evil which it is sometimes impossible to avoid, as in the case of almost simultaneous publication; but in due time the later name is relegated to the list of synonyms and gives little further trouble. It does not seem to me that any change or additions to the present rules of nomenclature are needed. Naturalists very soon decide on the relative value of names, but always with due regard to the law of priority; it is a misfortune, perhaps, that this law is sometimes pushed too far, as in the case either of forgotten authors, or of doubtful descriptions. The alteration of trivial names from two authors using the same word is a case of very rare occurrence.

FRANCIS P. PASCOE

The so-called "Meteor-cloud" of Feb. 5

YOUR correspondent, Captain S. P. Oliver, appears to have been mistaken as to the character of the phenomenon seen by him on February 5, and noticed in NATURE (vol. ix. p. 313). At the hour he has indicated, the somewhat rare phenomenon an auroral arch was formed, which remained visible for about half an hour, and is doubtless the luminous "meteor cloud" seen by him. The description Captain Oliver has given of it is sufficiently accurate, though he does not mention that it drifted slowly southward, a well-known characteristic of the phenomenon. Its direction was of course at right angles to the magnetic meridian, and its position in the heavens, as seen from this locality, was more northward than that observed by your correspondent. During the whole time that I observed it, the arch crossed some portion of the constellation Ursa Major, the star δ Ursæ Majoris being in its midst when first seen, and the entire arch having retreated southward as far as ζ Ursæ Majoris before it disappeared. It was of uniform breadth and intensity, and spanned the sky from west to east (magnetic), passing not much to the north of the zenith. Although I have been fortunate enough to have seen auroral arches upon several occasions, and once succeeded in obtaining the spectrum, I have never seen a brighter or more complete arch than this one; but what made it quite unique, at least as far as my experience goes, was the fact that the ordinary aurora with a well-defined "dark segment" was visible in the north-north-west at the same time, from which, at an earlier period, brilliant streamers had proceeded. There were therefore two parallel arches of light at an interval of perhaps 50° from one another, which the slow movement of the upper one gradually increased. The night was remarkably clear, and the zodiacal light had been plainly visible earlier in the evening.

The Observatory, Durham, Feb. 21

Aboriginal Australian Artists

I NOTICED, in one of your latest papers, that some of your readers doubted the ability of Australian, or other low savages, to sketch in the manner of the Vezère people, and I made a copy of a few sketches still found in this neighbourhood engraved on rocks. They consist chiefly of fishes, whales, birds, and a few men; the execution is not so good as when the figures are scratched on blackened bark. I also send you a photograph of a carving in fossil coral from New Guinea. H.M.S. *Basilisk* has not long ago returned from New Guinea, and brought some splendid weapons, &c.; also one of the Papuan pigs, which they brought for our collection. It is the most intelligent pig I have ever seen, follows me like a dog, and goes up to the very top of the Museum building, which is about 80 feet high.

I noticed the, to me, wonderful remark about a scarcity of skeletons of large carnivora in European museums, and I am glad to say that we possess two tigers, two lions, wolf, hyæna, three grey seals, two large sperm whales, 70 and 35 feet in length, many small birds, dugongs, &c. &c. The sum total of our skeletons, all mounted, is more than 150; with few exceptions all articulated on the premises by one man, who has never been out of Sydney in his life. If our Government grant some extra money for cabinets, I think we shall be able to astonish the people on board the *Challenger* when they come here, because half our Australian fossils and minerals cannot be exhibited for want of the necessary cases.

GERARD KREFFT

P.S. The trustees have had so many applications for *Ceratodus* specimens, and they have been so often disappointed when exchanging them with other museums, that they have now determined to sell their duplicates in London to the highest bidders. Five of these fishes, in spirits (males and females) will be despatched to Messrs. P. W. Flower and Sons, and I hope that a good price will be obtained for them. Up to the present time all efforts to obtain more of the *Ceratodus* have been in vain, and I believe that they are not so common as some people think. Mr. George Masters has too much to do here; and besides, we have no funds, travelling being very expensive in the Wide Bay district, otherwise another Expedition would be sent by the Board. Mr. Masters knows *how* to catch them, and I hope that when the *Challenger* arrives he will be able to accompany a party from that ship to Gayndah.

Rainbow and its Reflexion

A FEW weeks ago I had the pleasure of seeing a rainbow and its reflexion, or at least a reflexion of one from the same shower at the same time, in smooth water.

The base of the bow in the cloud seemed but a few hundred yards from me, and the reflexion evidently did not belong to it, as the two bases did not correspond, the reflected bow lying inside the other, the red of the one commencing where the violet rays of the other disappeared.

Balbriggan, Ireland, Feb. 2 GEORGE DAWSON

Remarkable Fossils

THE letter by Mr. T. W. Cowan in NATURE, vol. ix. p. 241, confirms the truth of the statements contained in my "Appeal to our Provincial Scientific Societies" which appeared in NATURE, vol. ix. p. 162. Collections of the kind described by Mr. Cowan are "kicking" about the country in all directions, valued merely as temporary possessions by the owners, few of whom, as far as my experience goes, appear to possess sufficient public spirit or intelligence to realise their public and scientific importance; otherwise these collections would be more frequently localised and preserved for the district museum.

Jan. 31 S. G. P.

Volcanoes and the Earth's Crust

MR. HOWORTH, in NATURE, vol. ix. p. 201, advances the following opinions:—That volcanoes are found neither in regions of elevation nor of subsidence, but on the boundaries between them; that the great continents are on the whole rising, and the beds of the great oceans on the whole sinking; and that the centres of elevation are in the circumpolar regions.

It seems to me that the last two statements cannot be reconciled with each other. The southern hemisphere is for by far the greater part oceanic. According to Mr. Howorth, the ocean-beds are subsiding, and yet the southern circumpolar region contains a focus of elevation. Further: if volcanoes are not found in areas of elevation, and if the circumpolar regions are regions of elevation, what does he make of the volcanoes of Jan Mayen (between Norway and Spitzbergen), and of the Antarctic continent?

Were there any such laws of elevation and subsidence as Mr. Howorth maintains, the respective regions of elevation and of subsidence would have continued the same since the consolidation of the earth: but this is contradicted by the commonest facts of stratification, which show that elevation and subsidence have everywhere alternated with each other.

The Use of Terms in Cryptogamic Botany

As no specialist in Algology has replied to the inquiry of your correspondent "D. R.," in NATURE for January 15, I may be permitted to quote for his information the following from the article "Nucleus," in the "Treasury of Botany" from the pen of the author of the "Introduction to Cryptogamic Botany":—"In Algæ the term is applied to the fructifying mass of the Rhodosperms, whether contained in a single cell or in a compound cyst or conceptacle, the word *nucleoli* being used when there is a group of nuclei." The instance alluded to by your correspondent is, unfortunately, not the only one in which the terminology of cryptogams is in a state of most perplexing confusion.

ALFRED W. BENNETT

A Lecture Experiment

THE condensation of liquid in the form of vapour into minute globules, and the production of a shower of rain, may be very well illustrated for class purposes in the following manner:—

Place about an ounce of Canada balsam in a Florence flask, and let it boil. At the top of the flask clouds of globules of turpentine will be seen hovering about, altering in shape very much like sky-clouds, and the globules are large enough to be visible by the naked eye. If a cold glass rod be gradually introduced into the flask, these clouds may be made to descend in showers. By the adaptation of a lime-light the whole process could be shown on a screen.

LAWSON TAIT

TODHUNTER ON EXPERIMENTAL ILLUSTRATIONS

Segnius irritant animos demissa per aurem,
quam quæ sunt oculis subjecta fidelibus, et quæ
ipse sibi tradit spectator.

THE following is, as nearly as I can recollect, the substance of a few remarks which I felt myself compelled to make to my class in a recent lecture. I had exhibited and described Hope's apparatus for showing the maximum density point of water, and proceeded to say:—

Now that the freezing mixture has been applied, my assistant will from time to time record on the black-board the simultaneous indications of the two thermometers, and will recall our attention to the experiment as the critical period approaches. You must, however, in this form of experiment take for granted his fidelity and accuracy in reading and recording. By means of a somewhat cumbrous application of optical processes, it would be easy to project upon a screen images of the thermometers, in such a way that each of you might see for himself the course of the phenomenon. But the thermo-electric method, whose principle I have already explained to you, is at once far easier of application, and in its indications more directly expressive. This I will show on another occasion. For the present you must rely on the observations to be made for you by my assistant. Yet I have no doubt that all of you will allow that the exhibition of the experiment, even in this imperfect manner, wonderfully assists you in understanding its nature.

This leads me to mention that a very decided opinion against the use of experimental illustration has been recently pronounced by one of the most erudite and voluminous of British mathematicians; my own former tutor, Mr. Todhunter, whose name and many of whose works must be familiar to most of you. Such a man speaks, deservedly with authority, on many points; and therefore his dicta upon a point with which he shows himself to be totally unacquainted are especially dangerous. And I feel that it is my duty to point out to you, and warn you against, errors or absurdities connected with physics, whenever they come from one whose statements are, on other grounds, worthy of attention. I shall not trouble you with the whole passage I refer to in Mr. Todhunter's "Conflict of Studies," but merely read to you a sentence or two of the most astounding part of it. I premise that though he is speaking of the teaching of physical science in schools, his observations apply (if they have any basis whatever) to science-teaching in general.

"It may be said that the fact makes a stronger impression on the boy through the medium of his sight, that he believes it the more confidently. I say that this ought not to be the case. If he does not believe the statements of his tutor—probably a clergyman of mature knowledge, recognised ability, and blameless character—his suspicion is irrational, and manifests a want of the power of appreciating evidence, a want fatal to his success in that branch of science which he is supposed to be cultivating."

Verbal comment on this would be altogether superfluous, and the only practical comment I am disposed now to make is to proceed at once to farther *experimental* illustrations of the subject before us.

P. G. TAIT

POLARISATION OF LIGHT *

V.

THE conversion of plane into circularly polarised light may also be effected by total reflexion. If plane-polarised light traversing glass be incident upon the inner side of the limiting surface at any angle at which total reflexion takes place, it may be considered as resolved into two plane-polarised rays, the vibrations of one being parallel and those of the other perpendicular to the plane of reflexion; and there is reason to believe that in every such case a difference of phase is brought about which for a particular angle in each substance (in St. Gobain glass it is 54° 30′) it has a maximum value of one-eighth of a wave-length. And if the original plane of vibration be inclined at an angle of 45° to that of reflexion the amplitudes of the two vibrations, into which the reflected vibrations are supposed to be resolved, will be equal. A full discussion of the mechanical causes which may be considered to effect this difference of phase would carry us deeper into the more difficult parts of the Wave Theory than would be suitable in this place. But if we accept the fact that the above-mentioned effects result, when polarised light (whose plane of vibration is inclined at 45° to that of reflexion) is reflected at a proper angle; then the following construction will be readily understood. Take a rhomb of glass, *a, b, c, d*, Fig. 14, whose acute angles are 54° 30′; a ray incident perpendicularly to either end will undergo two total internal reflexions at the sides, say at *p* and *s*, and will emerge perpendicularly to the other end. These two reflexions will together produce a retardation, as described above, of one-fourth of a wave-length. And if the ray be originally polarised and its plane of vibration be inclined

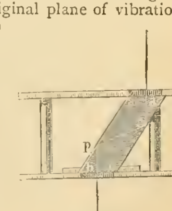

FIG. 14.

* Continued from p. 285.

at an angle of 45° to that of reflexion (that of the paper in the figure) the amplitudes of the two vibrations will be equal; and all the conditions will be fulfilled for the production of circular polarisation. Such an instrument was invented by Fresnel, and is called in consequence Fresnel's rhomb. On account of its length and its displacement of the ray, it is not so convenient as a quarter-undulation plate; but on the other hand it affects rays of all wave-lengths equally, while the quarter-undulation plate can strictly be adapted to rays of only one wave-length.

If either of these instruments be introduced and suitably placed between a selenite plate and the analyser, the chromatic effects will be similar to those due to a plate of quartz cut perpendicularly to the axis.

Another important property of these instruments consists in their effect upon circularly polarised light. Such light may be considered to arise from two plane-polarised rays whose vibrations are perpendicular to one another, and which present a difference of phase equal to a quarter of a wave-length. If, therefore, either a quarter-undulation plate or a Fresnel's rhomb be suitably placed, it will either increase or diminish the difference of phase by a quarter of a wave-length. In the one case the difference of phase will amount to a half wave-length, in the other it will vanish. And in either case the vibration will be converted into a rectilinear one; but the directions of vibration in the two cases will be perpendicular to one another.

Reflexion from a metallic surface may also be employed for converting plane into circular polarisation. If a ray of plane-polarised light fall upon a metallic reflector it is divided into two, whose vibrations are respectively parallel and perpendicular to the reflector; and the latter is retarded behind the former by a difference of phase depending upon the angle of incidence. If the plane of vibration of the incident ray be inclined to the plane of incidence at an angle (nearly 45°) which varies with the metal employed, but which is perfectly definite, the intensities become equal. And further, if the angle of incidence have a particular value dependent upon the nature of the metal (for silver 72°) the retardation will amount to a quarter of a wave-length. And the result will be a circularly polarised ray as in the case of total reflexion.

The apparatus (Fig. 15) best adapted for experiments based upon this principle is a modification of Norremberg's polariscope, suggested by Sir Charles Wheatsone, from whom the following description is quoted:—

"A plate of black glass, G, is fixed at an angle of 3° to the horizon. The film to be examined is to be placed on a diaphram, D, so that the light reflected at the polarising-angle from the glass plate shall pass through it at right angles, and, after reflexion at an angle of 18° from the surface of a polished silver plate S, shall proceed vertically upwards. N is a Nicol's prism, or any other analyser, placed in the path of the second reflexion. The diaphragm is furnished with a ring, moveable in its own plane, by which the crystallised plate to be examined may be placed in any azimuth. C is a small moveable stand, by means of which the film to be examined may be placed in any azimuth and at any inclination; for the usual experiments this is removed.

"If a lamina of quartz cut parallel to the axis, and sufficiently thin to show the colours of polarised light, be placed upon the diaphragm so that its principal section (*i.e.* the section containing the axis) shall be 45° to the *left* of the plane of reflexion, on turning the analyser from left to right, instead of the alternation of two complementary colours at each quadrant, which appear in the ordinary polarising apparatus, the phenomena of successive polarisation, exactly similar to those exhibited in the ordinary apparatus by a plate of quartz cut perpendicularly to the axis, will be exhibited; the colours follow in the order R, O, Y, G, B, P, V, or, in other words, ascend as in the case of a right-handed plate of quartz cut perpendicularly to the axis. If the lamina be now either inverted, or turned in its own plane 90°, so that the principal section shall be 45° to the right of the plane of reflexion, the succession of the colours will be reversed, while the analyser moves in the same direction as before, presenting the same phenomena as a left-handed plate of quartz cut perpendicularly to the axis. Quartz is a positive doubly refracting crystal; and in it consequently the ordinary index of refraction is smaller than the extraordinary index. But if we take lamina of a negative crystal, in which the extraordinary index is the least, as a film of Iceland spar split parallel to one of its natural cleavages, the phenomena are the reverse of those exhibited by quartz: when the principal section is on the *left* of the plane of reflexion the colours descend, and when it is on the *right* of the same plane the colours ascend, the analyser being turned from left to right.

"It has been determined that the ordinary ray, both in positive and negative crystals, is polarised in the principal section,* while the extraordinary ray is polarised in the section perpendicular thereto. It is also established that the index of refraction is inversely as the velocity of transmission. It follows from the above experimental results, therefore, that when the resolved ray whose plane of polarisation is to the left of the plane of reflexion is the quickest, the successive polarisation is right-handed, and when it is the slowest, the successive polarisation is left-handed—in the order R, O, Y, G, B, P, V and in the second case in the reverse order.

"The rule thus determined is equally applicable to laminæ of bi-axal crystals.

"As selenite (sulphate of lime) is an easily procurable crystal and readily cleavable into thin laminæ capable of showing the colours of polarised light, it is most frequently employed in experiments on chromatic polarisation. The laminæ into which this substance most readily splits contain in their planes the two optic axes; polarised light transmitted through such laminæ is resolved in two rectangular directions, which respectively bisect the angles formed by the two optic axes; the line which bisects the smallest angle is called the intermediate section; and the line perpendicular thereto which bisects the supplementary angle is called the supplementary section. These definitions being premised, if a film of selenite is placed on the diaphragm with its intermediate section to the left of the plane of reflexion, the successive polarisation is direct or right-handed; if, on the contrary, it is placed to the right of that plane, the successive polarisation is left-handed. The ray polarised in the intermediate section is therefore the most retarded; and as that section is considered to be equivalent to a single optic axis, the crystal is positive.

"In one kind of mica the optic axes are in a plane perpendicular to the laminæ. They are inclined 22½° on each side the perpendicular within the crystal, but, owing to the refraction, are seen respectively at an angle of 35°·3 therefrom. The principal section is that which contains the two optic axes. If the film is placed on the diaphragm with its principal section inclined 45° to the left of the plane of reflexion, the successive polarisation is right-handed. The ray, therefore, polarised in the section which contains the optic axes is the one transmitted with the greatest velocity.

"Films of uni-axal crystals, whether positive or negative, and of bi-axal crystals, all agree therefore in this respect:—that if the plane of polarisation of the quickest ray is to the left of the plane of reflexion, the successive polarisation is right-handed when the analyser moves from left to right; and if it is to the right of the plane of reflexion, other circumstances remaining the same, the successive polarisation is left-handed.

* The plane of polarisation is, throughout these pages, taken to be perpendicular to that of vibration.

"It must be taken into consideration that the principal section of the film is inverted in the reflected image; so that if the plane of polarisation of the quickest ray in the film is to the left of the plane of reflexion, it is to the right of that plane in the reflected image.

"It may not be uninteresting to state a few obvious consequences of this successive polarisation in doubly refracting laminæ, right-handed and left-handed according to the position of the plane of polarisation of the quickest ray. They are very striking as experimental results, and will serve to impress the facts more vividly on the memory.

"1. A film of uniform thickness being placed on the diaphragm with its principal section 45° on either side the plane of reflexion, when the analyser is at 0° or 90° the colour of the film remains unchanged, whether the film be turned in its own plane 90°, or be turned over so that the back shall become the front surface; but if the analyser be fixed at 45°, 135°, 225°, or 315°, complementary colours will appear when the film is inverted from back to front, or rotated in its own plane either way 90°.

"2. If a uniform film be cut across and the divided portions be again placed together, after inverting one of them, a compound film is formed, which, when placed on the diaphragm, exhibits simultaneously both right-handed and left-handed successive polarisation. When the analyser is at 0° or 90° the colour of the entire film is uniform; as it is turned round the tints of one portion ascend, while those of the other descend; and when the analyser is at 45° or $n90° + 45°$, they exhibit complementary colours.

"3. A film increasing in thickness from one edge to the other is well suited to exhibit at one glance the phenomena due to films of various thicknesses. It is well known that such a film placed between a polariser and an analyser will show, when the two planes are parallel or perpendicular to each other and the principal section of the film is intermediate to these two planes, a series of parallel coloured bands, the order of the colours in each band from the thick towards the thin edge being that of their refrangibilities, or R, O, Y, G, B, P, V. The bands seen when the planes are perpendicular are intermediate in position to those seen when the planes are parallel; on turning round the analyser these two systems of bands alternately appear at each quadrant, while in the intermediate positions they entirely disappear.

"Now let us attend to the appearances of these bands when the wedge-form film is placed on the diaphragm of the instrument, Fig. 15. As the analyser is moved round, the bands advance toward or recede from the thin edge of the wedge without any changes occurring in the colours or intensity of the light, the same tint occupying the same place at every half revolution of the analyser. If the bands advance toward the thin edge of the wedge, the successive polarisation of each point is left-handed; and if they recede from it the succession of colours is right-handed: every circumstance, therefore, that with respect to a uniform film changes right-handed into left-handed successive polarisation, in a wedge of the same substance transforms receding into advancing bands, and *vice versâ*. These phenomena are also beautifully shown by concave or convex films of selenite or rock-crystal, which exhibit concentric rings contracting or expanding in accordance with the conditions previously explained.

"4. Few experiments in physical optics are so beautiful and striking as the elegant pictures formed by cementing laminæ of selenite of different thicknesses (varying from $\frac{1}{2000}$ to $\frac{1}{60}$ of an inch) between two plates of glass. Invisible under ordinary circumstances, they exhibit, when examined in the usual polarising-apparatus, the most brilliant colours, which are complementary to each other in the two rectangular positions of the analyser. Regarded in the instrument, Fig. 13, the appearances are still more beautiful; for, instead of a single transition, each colour in the picture is successively replaced by every other colour. In preparing such pictures it is necessary to pay attention to the direction of the principal section of each lamina when different pieces of the same thickness are to be combined together to form a surface having the same uniform tint; otherwise in the intermediate transitions the colours will be irregularly disposed.

"5. A plate of rock-crystal cut perpendicular to the axis loses its successive polarisation, and behaves exactly as an ordinary crystallised film through which rectilinear polarised light is transmitted.

"By means of the phenomena of successive polarisation it is easy to determine which is the thicker of two films of the same crystalline substance. Place one of the films on the diaphragm E of the instrument (Fig. 15) in the position to show, say, right-handed polarisation, then cross it with the other film; if the former be the thicker, the successive polarisation will be still right-handed; if both be equal, there will be no polarisation; and if the cross film be the thicker, the successive polarisation will be left-handed. In this manner a series of films may be readily arranged in their proper order in the scale of tints.

"In the experiments I have previously described the planes of reflexion of the polarising mirror and of the silver plate were coincident; some of the results obtained when the azimuth of the plane of reflexion of the silver plate is changed are interesting.

"I will confine my attention here to what takes place when the plane of reflexion of the silver plate is 45° from that of the polarising reflector.

"When the principal sections of the film are parallel and perpendicular to the plane of reflexion of the polarising mirror, as the whole of the polarised light passes through one of the sections, no interference can take place, and no colour will be seen, whatever be the position of the analyser.

"When the principal sections of the film are parallel and perpendicular to the plane of reflexion on the silver plate, they are 45° from the plane of reflexion of the polarising mirror.

"The polarised ray is then resolved into two components polarised at right angles to each other; one component is polarised in the plane of reflexion of the silver plate, the other perpendicular thereto; and one is retarded upon the other by a quarter of an undulation.

"When the analyser is at 0° or 90° no colours are seen because there is no interference; but when it is placed at 45° or 135°, interference takes place, and the same colour is seen as if light circularly polarised had been passed through the film. The bisected and inverted film shows simultaneously the two complementary colours.

"But when the film is placed with one of its principal sections $22\frac{1}{2}°$ from the plane of reflexion of the polarising mirror, on turning round the analyser the appearances of successive polarisation are reproduced exactly as when the planes of reflexion of the silver plate and of the polarising mirror coincide. In this case the components of the light oppositely polarised in the two sections are unequal, being as cos $22\frac{1}{2}°$ to sin $22\frac{1}{2}$; these components respectively fall $22\frac{1}{2}°$ from the plane of reflexion of the silver plate and from the perpendicular plane, and are each resolved in the same proportion in these two planes. The weak component of the first, and the strong component of the second, are resolved into the normal plane, while the strong component of the first and the weak component of the second are resolved into the perpendicular plane.

"The apparatus (Fig. 15) affords also the means of obtaining large surfaces of uncoloured or coloured light in every state of polarisation—rectilinear, elliptical, or circular.

"It is for this purpose much more convenient than a Fresnel's rhomb, with which but a very small field of view can be obtained. It must, however, be borne in mind that the circular and elliptical undulations are inverted in the two methods: in the former case they undergo only a single, in the latter case a double reflexion.

"For the experiments which follow, the crystallised plate must be placed on the diaphragm E, between the silver plate and the analyser, instead of, as in the preceding experiments, between the polariser and the silver plate.

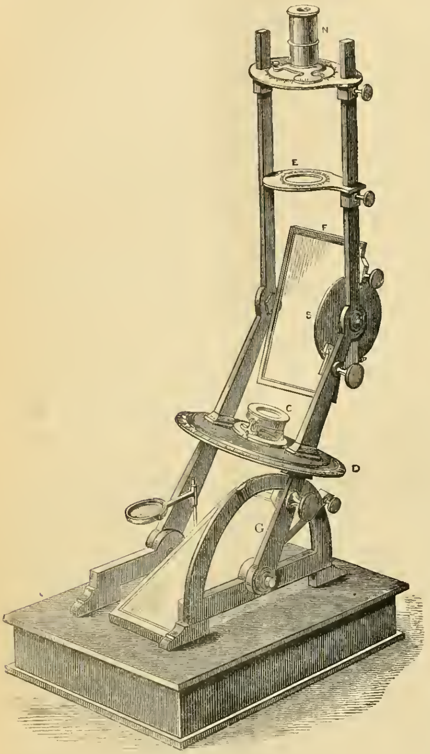

Fig. 15.—Wheatstone's modification of Norremberg's Polariscope.

"By means of a moving ring within the graduated circle D, the silver plate is caused to turn round the reflected ray, so that, while the plane of polarisation of the ray remains always in the plane of reflexion of the glass plate, it may assume every azithumal position with respect to the plane of reflexion of the silver plate. The film to be examined and the analyser move consentaneously with the silver plate, while the polarising mirror remains fixed.

"In the normal position of the instrument the ray polarised by the mirror is reflected unaltered by the silver plate; but when the ring is turned to 45°, 135°, 225°, or 315°, the plane of polarisation of the ray falls 45° on one side of the plane of reflexion of the silver plate, and the ray is resolved into two others, polarised respectively in the plane of reflexion and the perpendicular plane, one of which is retarded on the other by a quarter of an undulation, and consequently gives rise to a circular ray, which is right-handed or left-handed according to whether the ring is turned 45° and 225°, or 135° and 315°. When the ring is turned so as to place the plane of polarisation in any intermediate position between those producing rectilinear and circular light, elliptical light is obtained, on account of the unequal resolution of the ray into its two rectangular components.

"Turning the ring of the graduated diaphragm from left to right, when the crystallised film is between the silver plate and the analyser, occasions the same succession of colours for the same angular rotation as rotating the analyser from right to left when the instrument is in its normal position and the film is between the polariser and the silver plate."

The same principles apply to the case of bi-axal crystals cut parallel to a plane containing the two optic axes. A ray of plane-polarised light transmitted through such a plate is divided into two, whose vibrations respectively bisect the angles formed by the two axes. As mentioned above, the line which bisects the smallest angle is called the intermediate section, and the line perpendicular to it the supplementary section; and the order of the colours depends upon the relative velocity of the two rays. In selenite, the ray whose vibrations lie in the supplementary section is the slowest; in mica it is the swiftest. Hence these two crystals, all other circumstances being alike, give the colours in opposite orders, and may be regarded as positive and negative, like quartz and Iceland spar. And a test similar to that indicated for uni-axal may be applied to bi-axal crystals.

Some interesting and varied experiments may be made by using two circularly polarising instruments, *e.g.*, two quarter undulation plates (say the plates A and B), one between the polariser proper and the crystal (C) under examination, the other between the crystal and the analyser. The light then undergoes the following processes. If the plate A be placed so that its axis is at 45° on one side or other of the original plane of vibration, and the plate B with its axis parallel or perpendicular to that of A, then on turning the analyser we shall have the phenomena of circular polarisation described above. Again, if, the plates A and B retaining the positions before indicated, the crystal C be turned round in its own plane; then, since the light emerging from A and B is circularly polarised, it has lost all trace of direction with reference to the positions of polariser and analyser, and consequently no change will be observed.

Again, if the plates A and B have their axes directed at 45° on either side of the axis of C, and the three plates be turned round as one piece, the colour will remain unchanged, while if the analyser be turned, the colours will follow in the regular order. If the plates A and B have their axes directed at 45° on the same side of the axis of C, and the pieces be turned round bodily as before, the colours change in the same order as above, and go through their cycle once in every right angle of rotation; and if the analyser be turned in the same direction, the colours change, but in the reverse order. The explanation of this is to be found in the fact that when the plates A and B are crossed, the retardation due to A is compensated by that due to B; so that the only effective retardation is that due to the crystal C. But upon the latter depends the rotation of the plane of vibration; if, therefore, the polariser and analyser remain fixed, the colour will remain unaltered. When the plates A and B have their axes parallel, there is no compensation, and the colour will consequently change. It should be added that the rotation of the plane of vibration, and consequently the sequence of colours, does not follow exactly the same law in these cases as in quartz.

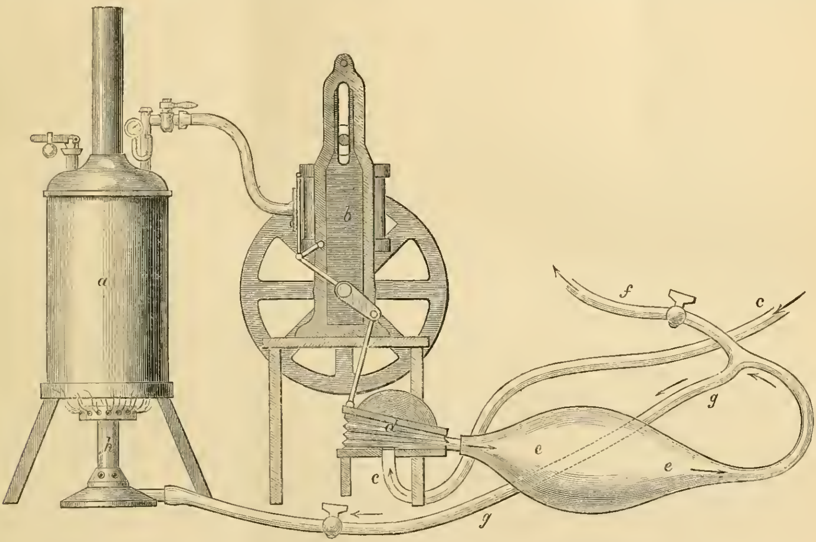
(*To be continued.*)

THE HEART AND THE SPHYGMOGRAPH*

IN the same way that by the spectroscope much can be learned as to the chemical constitution and the physical changes going on in the sun, so by the sphygmograph applied to the artery at the wrist many of the most important phenomena occurring in the heart can be studied with a facility that cannot be otherwise attained. Till the introduction of the sphygmograph of Marey the pulse was considered to be little more than a simple up and down movement, because the instruments employed to register it, such as those of Herisson, Ludwig, and Vierordt, developed so much momentum that the details of the true trace were disguised. In the instrument as at present employed, the substitution of counterbalancing springs instead of weights has so far improved its efficiency, that the pulse is now known to form a decidedly complicated curve if its movements are allowed to record themselves on a moving paper. The sphygmograph trace, as thus produced, gives indications in two directions; first, as to the action of the valves of the heart; and secondly, as to the manner in which the muscular walls of the ventricles perform their work. It is to the former of these subjects that most physiologists have directed their observations in employing the instrument; but it is to the latter, the more important of the two, that it is my intention to direct attention on the present occasion.

The heart being nothing more than a pump of a peculiar construction, much may be learned by comparing it with other artificially constructed machines for the same purpose. In most such machines the force which keeps the pump at work is constant in power, in other words it does not vary automatically in efficiency with the amount of work that is expected of it. In the locomotive engine, however, there is an arrangement by which the furnace becomes hotter as the speed at which it moves is increased, the waste steam pipe opening into the funnel and so varying the amount of the draught through the boiler tubes. With this arrangement it is nevertheless evident



Automatically Working-engine, when supplied with coal-gas.

that there is a great waste of fuel in the construction of the furnace.

It is quite possible to construct a steam-engine on much more economical principles, and the accompanying figure illustrates the manner in which the small engine on the table is at present working (see Figure). The boiler (*a*) being sufficiently heated, drives the engine (*b*), which performs work by pumping *coal-gas* from the tube *c* through the pump *d*, into the elastic reservoir *e*. From this elastic bag most of the coal-gas escapes, through the tube *f*, into an ordinary gas bag, but a tube (*g*) carries some of it to supply the Bunsen's burner (*h*) which heats the boiler. It is evident that with this arrangement the size of the flame of the Bunsen's burner (*h*), and therefore the pressure of steam in the boiler, which is the same as saying the efficiency of the engine, varies with the amount of work required of that engine; for the greater the pressure in the elastic bag, the harder is it for the engine to perform the work required of it, and the greater is the burner-flame. With a certain proportion between the sizes of the orifices of the taps and the extensibility of the elastic bag and tubes, it would be possible to arrange this engine in such a manner that, within certain limits, the velocity of the fly-wheel would not vary with the pressure in the elastic bag; in other words, with the work to be done. That the heart is a pump constructed on the same principle as this engine is the teaching of the sphygmograph, as far as it is in my power to interpret its curves, the proof resting on the following considerations.

First, the analogy between the anatomical distribution of the arteries and the different parts in connection with the engine is not difficult to trace. The coal-gas corresponds to the blood, the boiler (*a*) together with the engine (*b*) to the muscular tissue of the heart, whose left ventricular

* Abstract of a lecture delivered by Mr. A. H. Garrod at the Royal Institution on the evening of Friday, Feb. 6.

cavity has its analogue in that of the bellows (*d*). The elastic reservoir, together with the tubes, corresponds to the systemic arteries, the gas-bag connected with the tube *f* (the capillaries) to the systemic veins; and the tube *g* to the coronary arteries, which supply the muscular tissue of the heart with nutrient blood, just as it does the boiler by means of the burner *h*. This, however, does not show that the pumping power of the heart varies directly as the blood-pressure; that such is the case depends on the opportunity offered by the sphygmograph-trace for the estimation of the length of the ventricular systole under different circumstances. Each beat or revotion of the heart is divided into two main parts—(1) the period of contraction or systole, and (2) the period of repose or diastole. The former of these occupies the interval between the commencement of the primary rise and that of the dicrotic rise in the sphygmograph trace; the latter from the dicrotic rise to the commencement of the succeeding primary rise. In all good tracings from healthy pulses these two points, the primary and dicrotic rises, are readily found; and their relative lengths can be estimated with great accuracy. A large number of measurements have enabled me to prove that *the relative lengths of the systolic and diastolic portions of the pulse-trace do not vary for any given pulse-rate.* But, as will be granted by most physiologists who have worked at the subject, *the blood-pressure in the arteries is quite independent of the pulse-rate.* Consequently the heart may be doing very different amounts of work without any variation in the pulse-rate, which is the same thing as saying, with the same length of systole; which makes it evident that, as in the above-described engine, *the force of the cardiac muscular contraction varies directly as the blood-pressure*, knowing what we do about the flow of fluids through capillary tubes, and the capacity of the arterial system under different degrees of blood-pressure.

The sphygmograph trace tells us more than this. Though the length of the systolic portion of the beat does not change with any given pulse-rate, nevertheless it does so greatly with different rapidities of pulse; my observations showing that the length of the systole varies as the cube root of the whole beat, being found from the equation $xy' = 47 \cdot \sqrt[3]{x}$ when $x =$ the pulse-rate and $y' =$ the ratio borne by the systole to the whole beat. From this no other inference can be drawn than that the length of the diastole, or period of cardiac rest, during which fresh blood is circulating through the ventricular walls, must modify the contractile force of its muscular substance. The exact extent of this influence can be more readily estimated by a study of the cardiograph trace, which is obtained by applying the sphygmograph to the side of the chest at any spot where the pulsations of the heart are to be felt. It may, from the thus obtained curves, be demonstrated that if not exactly, approximately, at least, *the nutrition of the heart's walls must vary as the square-root of the length of the diastolic period.**

There is much, therefore, as I hope I have been able to show, to be learned respecting the action of the heart from measurement of sphygmograph tracings, and it is scarcely too bold to extend the generalisation to the properties of muscular tissue generally; for the fact that each beat depends entirely for its efficiency on the peculiarities in the blood-pressure and the duration of the previous diastole, removes all complications as to incompleteness of exhaustion, and all doubts as to the exact amount of work done by the muscular fibres themselves of that most perfect of engines, whose extreme perfection enables it to complete in most of us something like 750,000 beats in a week, and nearly thirty thousand million revolutions in a person by the time he is seventy years of age.

* *Journal of Anatomy and Physiology*, May and November, 1873.

*DR. VON MIKLUCHO MACLAY'S RESEARCHES AMONG THE PAPUANS **

WHEN lately at Buitenrovg—the scarcely euphonious equivalent of the "Sans Souci" of a former English Governor of Java—we had the good fortune to make the acquaintance of the owner of a name, whose peculiarity, no less than fame, has rendered it familiar to every biologist.

The friends—and we are sure they must be numerous—of Dr. Miklucho Maclay will regret to hear that he is determined, in spite of an aguish fever which still clings to him, and of, it is feared, some serious implication of the liver, to start again in a few days for the scene of his recent labours—the east coast of New Guinea, where he had previously spent fifteen months in close intercourse with the natives.

On September 19, 1871, the Russian corvette *Vitias* cast anchor in Astrolabe Gulf, and Dr. Maclay landed with two servants, one a Polynesian, the other a Swede. After a hut of very modest dimensions† had been built for him by the ship's carpenter, the *Vitias* weighed anchor on the 26th, and departed.

Dr. Maclay was soon left practically alone, and dependent entirely upon himself, for the Polynesian servant died early in December of a chronic fever which he had when he started, and the Swede soon followed suit, with the exception, that he did not die, but by constant ailing was a source of much encumbrance to his master.

As the natives were very distrustful, scarcely answering any questions, Dr. Maclay did not make much progress with the essential task of learning the language. Not only, however, were they suspicious, but determined to discourage the presence of the stranger by shooting arrows close to his head and neck, and pressing their spears so hard against his teeth, that he was constrained to open his mouth. Finding that he did not only not take the least notice of these annoyances, but that all his actions toward them were good (for, he being a doctor, his utility in the economy of the community was soon discovered), they concluded that he was no ordinary mortal, but that he was the veritable man-in-the-moon ("Kàramtâmo"), and paid him due respect accordingly.

As there were footpaths only in the neighbourhood of the villages, and as these latter were never found at a greater elevation than 1,500 feet, Dr. Maclay had some difficulty in making expeditions without guides, which at first were difficult to procure.

During his stay in New Guinea Dr. Maclay studied the inhabitants of the whole coast of Astrolabe Gulf; the people of the mountains round the gulf, and the dwellers on the islands near Cape Duperré, one of the boundaries of the gulf, who lived a life of such perfect peace that he called the islands "the Archipelago of Contentment." ‡ The inhabitants, too, of Dampier Island (Kar-kar) paid him visits. The inhabitants of "Maclay Coast," by which name Dr. Maclay proposes to call the coast skirting the edge of the Astrolabe Gulf, were of especial interest, as it seems that they have never been in intercourse with any civilised people, for not only were all their tools and weapons made out of stone, wood, or bone, but no trace of any European article could be found among them. These people treasured up, or exchanged as valuable, the smallest trifles which were given them, *e.g.* fragments of broken bottles, with which they shaved themselves, as a substitute for flint, or the sharp edges of grasses.

* "Anthropologische Bemerkungen ueber die Papuas der Maclay Küste in Neu Guinea." Reprint from the *Naturkundig Tijdschrift voor Nederlandsch Indie Deel* xxxiii. *Mijn Verblijf aan de Oostkust van Nieuw Guinea. Ibid.* (Batavia, 1873).

† Only 7 feet broad, and 14 feet long, and divided by a screen of sailcloth into two rooms, one for his servants, the other for himself. The hut was situated on the south coast of Astrolabe Gulf, midway between the two capes, its boundaries.

‡ "Archipel der zufriedenen Menschen."

Dr. Maclay told us of one curious custom which he does not mention in either of the two papers referred to in the note. The Papuans, though they know how to produce fire by rubbing together two pieces of wood, do not do this when they require this agent, but always carry their fire literally about with them, either trailing a lighted stick after them as they walk, or placing the same under their beds when they sleep.

Dr. Maclay, despite much pains, was only able to collect ten skulls, and only two out of these had the lower jaw, for the natives preserve this with great veneration, while the skull itself is thrown into the neighbouring jungle as a thing of no worth. The skull of the Papuans of Maclay coast is "dolicho-cephalic." The superciliary eminences are frequently very strongly developed The maxillary region is prognathous, so that the upper teeth project considerably beyond those of the mandible. The Papuans are of middle stature, the females being considerably smaller than the males, but are strong and well built.

Contrary to what has been written, there is no roughness of skin considerable enough to constitute a race characteristic ; which may be largely accounted for by the custom of smearing the bodies with a kind of earth, and to the frequency of psoriasis ("masso"). The colour of the skin too is in general of a light chocolate brown, and not of a bluish-black colour as has been previously asserted. The inhabitants of New Ireland, an island not far distant, have, on the other hand, a comparatively dark skin. The scars of slight wounds, *e.g.* such as are made with a red-hot coal, are somewhat darker than the surrounding skin, while deep wounds, which are of not infrequent occurrence, leave behind them scars almost white in colour.

After a series of very careful observations, made as well upon shaven as upon well-covered scalps, Dr. Maclay concludes that the hair is not naturally disposed, as has been represented, in tufts or clumps, but grows just as it would upon the head of a European. The length of the hair, too, varies in different individuals, for while one man is fain to cover his bald pate with a cuscus,* another is proud to display a "gatessi," which luxuriantly covers his shoulders.†

The natural colour of the hair is dull black, but this is marked, after the period of childhood, by a black ("kuma") or red ("surru") dye. The hair of children is covered with a wash of ashes and water for protection against lice ; this hardens into a thick crust. In the case of males this is continued till the time of circumcision, after which period much care is bestowed upon the coiffure. The women, oddly enough, expend no pains upon the arrangement of their hair. The eye-brows are generally shaven, and the hairs of the beard are either shaven or plucked out in the young men, but are permitted to grow among adults.

The general hair-growth upon the body seems to be more scanty than it is among the Caucasian races. Though hair is never seen on the back of the hands, it sometimes grows pretty thickly along the line of the vertebral column, and is sometimes so far extended as to cover the whole of the buttocks.

With regard to the physiognomy, the forehead is not high but small, and sometimes retreating ; the nose is broadly flattened out, frequently with dilated nostrils ; the mouth is broad, and has a projecting upper lip ; the chin is retreating, while strongly projecting cheek-bones strikingly contrast with the smallness of the forehead in the temporal region.

The Papuans of Maclay coast bore a hole through the septum of the nostrils, in which a long fragment of stone or piece of shell is worn. The teeth are much worn through the almost exclusive use of a vegetable diet : Dr. Maclay noticed this in his own teeth after a stay of eight months in Papua. The lobules of the ears are pierced at an early age by means of the thorn of a *Dioscorea* and become much elongated by having to support heavy ear-rings.

If the back of a Papuan is seen in profile, there will be noticed a considerable concavity of curve in the lumbar region. This would seem to be a characteristic in which the Papuan differs from the Caucasian race. The Papuans make a greater use of the left hand and arm than of the right, and use the feet to pick up various objects—sometimes very small ones—from the earth. This is done, not by flexion of the toes, but by anadduction of the great toe, which is considerably separated from the rest of the toes. From this use of the,toes, it frequently happens that the two feet are dissimilar in size.

Circumcision is performed at from the ages of 13 to 15 years, and, as Zipporah performed it, with a sharp flint. This custom is general among the Papuans of Maclay coast, and among most of the coast and some of the mountain inhabitants. Those—and among them are the New Irelanders and the inhabitants of one of the Islands of the Archipelago of Contentment—who do not use this rite are looked down upon by their circumcised brethren. The suckling of infants is carried on for a long period, sometimes to the age of four years.

The Papuans are very strict in their sexual relations. The men marry early, soon after circumcision, and have only one wife ; concubinage is almost unknown. The women, probably on account of the hard work in which they are engaged, seldom bear many children.

In spite of the dark colour of their skin, Dr. Maclay was able to recognise a change of colour in the face among the Papuans. He does not, however, state whether blushing follows upon a sense of shame, but only notices that the features are darker when they are overjoyed, or have been making great efforts, *e.g.* in the dance.

The Papuan women, like their European sisters, cultivate the art of which Mr. Turveydrop was the distinguished professor. Readers of the "Arabian Nights may remember how that the seductive wriggling of the sides of one of the damsels "shaped like the letter alif," caused the "world to turn black" before the eye of a susceptible hero, and will therefore fully appreciate the subtle influence of a peculiar and "killing" wriggle which the Papuan maid begins to have at even the tender age of seven years. The half-caste women whom one sees at Batavia seem to have adopted a similar though modified habit.

The favourite position of the Papuan men—as it seems to be among the Malays also—is resting the buttock upon the heels (*das Hocken*), while the whole surface of the soles of the feet is applied to the ground. Dr. Maclay found that he could keep his balance only when the toes alone were in contact with the earth. This position of the Papuan must not only be acquired, but must depend also upon a peculiar relation of proportion in the limbs. Nothing can be said with certainty as to the duration of life among the Papuans. Dr. Maclay never saw an old individual among them.

Dr. Maclay, from the observations which he has at present made, concludes that *the Papuan stock falls into numerous varieties, distinct from one another, which, however, have no sharp lines of demarcation.*

On December 19, 1872, some natives came to Dr. Maclay to inquire the cause of some smoke which had been seen rising from the sea between Vitias and Dampier Islands. This turned out to be the clipper *Izoumroud*, which had been sent out to look for the traveller (whose death, it seems, had been announced in the English journals), at the instance of the Grand Duke Constantine.

Early on the morning of the 24th the *Izoumroud* weighed anchor, and as she steamed away there could

* A small marsupial found in Papua. It is figured in Wallace's "Malay Archipelago."

† The long hair worn at the back of the head is termed "gatessi."

be heard all along the coast the sound of the Bâroem, a great wooden gong, announcing to the islanders the departure of the "man-in-the-moon," who had taken up his abode for more than a year amongst them.

JOHN C. GALTON

MICROSCOPIC EXAMINATIONS OF AIR

A WORK* of the greatest importance on the above subject has just been published in Calcutta by Mr. Douglas Cunningham. The conclusions which he has reached as the result of the experiment are so valuable that we deem it right to give them as great publicity as possible. The following is Mr. Cunningham's description of the aeroscope with which he made his experiments:—

The apparatus employed in obtaining specimens was a slightly modified form of that devised by Dr. Maddox. It consisted of three thin brass tubes, two of which slipped over the third central one and came into contact with the opposite side of a projecting rim on its circumference. This rim was formed by the margin of its diaphragm which divided the centre tube into two chambers. It was of sufficient thickness to allow of a spindle passing up through it. The latter terminated in a pointed extremity, which came in contact with the upper end of the bearing, and provided for the free rotation of the system of tubes. Round the margin of the diaphragm there was a set of perforations, to allow of the passage of air through it, and, on the centre of its anterior surface, there was a square plate of glass with a slightly projecting rim on its lower margin. The anterior of the two lateral tubes was provided with an expanded orifice, and contained a small, finely-pointed funnel in its interior; the pointed extremity opening immediately in front of the centre of the diaphragm-plate. The posterior tube was quite simple, and had a good-sized fish-tail vane fitted into a slit in its extremity.

The following are Mr. Cunningham's conclusions:—

The most important conclusions to be derived from all the preceding experiments regarding the dust contained in the atmosphere in the vicinity of Calcutta appear to be the following:—

1. The aeroscope affords a very convenient method for obtaining specimens really representing the nature of the true atmospheric dust.

2. Specimens of dust washed from exposed surfaces cannot be regarded as fair indices of the constituents of atmospheric dust, since they are liable to contain bodies which may have reached the surface otherwise than by means of the air, as well as others which are the result of local development.

3. Specimens collected by gravitation also fail to indicate the nature and amount of organic cells contained in the atmosphere, as the heavier amorphous and inorganic constituents of the dust are deposited in relative excess due to the method of collection.

4. Dew also fails to afford a good means of investigating the subject, as it is impossible to secure that all the bodies really present in a specimen of it should be collected into a sufficiently small space, and, moreover, because it is liable to accidental contaminations, and also affords a medium in which rapid growth and development are likely to take place.

5. Distinct infusorial animalcules, their germs or ova, are almost entirely absent from atmospheric dust and even from many specimens of dust collected from exposed surfaces.

6. The cercomonads and amœbæ appearing in certain specimens of pure rain-water appear to be zoospores developed from the mycelial filaments arising from common atmospheric spores.

7. Distinct bacteria can hardly ever be detected among the constituents of atmospheric dust, but fine molecules of uncertain nature are almost always present in abundance; they frequently appear in specimens of rain-water collected with all precautions to secure purity, and appear in many cases to arise from the mycelium developed from atmospheric spores.

8. Distinct bacteria are frequently to be found amongst the particles deposited from the moist air of sewers, though almost entirely absent as constituents of common atmospheric dust.

9. The addition of dry dust, which has been exposed to tropical heat, to putrescible fluids is followed by a rapid development of fungi and bacteria, although recognisable specimens of the latter are very rarely to be found in it while dry.

10. Spores and other vegetable cells are constantly present in atmospheric dust, and usually occur in considerable numbers: the majority of them are living and capable of growth and development; the amount of them present in the air appears to be independent of conditions of velocity and direction of wind; and their numbers are not diminished by moisture.

11. No connection can be traced between the numbers of bacteria, spores, &c., present in the air and the occurrence of diarrhœa, dysentery, cholera, ague, or dengue; nor between the presence or abundance of any special form or forms of cells, and the prevalence of any of these diseases.

12. The amount of inorganic and amorphous particles and other *débris* suspended in the atmosphere is directly dependent on conditions of moisture and of velocity of wind.

If these results be compared with those obtained by other observers, and detailed in the first section of this report, it will be seen that they agree very closely with those of M. Robin, only differing from them in indicating the presence of a somewhat larger number of spores than appeared in his observations. They differ almost equally from those arrived at by Pouchet and Ehrenberg. It is somewhat difficult to understand how the former observer so constantly failed to detect the presence of spores in his experiments, but there is an apparent reason for Ehrenberg's observation of the predominance of animal forms in the atmosphere. His conclusions appear to have been almost entirely founded on the results of the examination of specimens of dust not directly obtained from the air, but from surfaces on which it had been previously deposited from the air, such as leaves, tufts of moss, &c. Now, as has already been indicated, it is certainly quite unwarrantable to assume that all organisms found in such specimens existed as such in the air, or were even derived from the air in any way. All such surfaces are more or less liable to contact-inoculation; leaves and moss, for example, are liable to this through the agency of insects or birds. Moreover, with regard to many of the organisms detected in such situations, it must be recollected that there is no reason why they should not have arrived there by means of active progression over the surface. When surfaces are wet with rain, there is no reason why Tardigrades, Rotifers, Anguillulæ, and many infusoria should not travel over them from one point to another. The journey accomplished at any one time may be small, and its progress soon arrested by defective moisture; but, unless they are deprived of vitality in the interval by desiccation, they are ready for a fresh start when favourable conditions are again presented to them.

It is hardly safe to venture on the vexed questions regarding the origin of bacteria, but it may, at all events, be stated that the results of the present experiments are certainly not opposed to the belief in the transmission of these organisms in some way or other by means of the atmosphere; for they were actually observed among the particles in moist air, the addition of dry dust to putre-

* "Microscopic Examinations of Air," by D. Douglas Cunningham, M.B. Surgeon H.M. Indian Medical Service (Calcutta).

scible fluids was followed by their rapid development, and they appeared in specimens of pure rain water.

Although these observations may not appear to encourage the hope of success in discovering the presence of atmospheric particles connected with the origin of disease, it must not be forgotten that they only refer to bodies distinguishable from one another *whilst in the air*, the possibility remaining that many of the finer molecules present in it are really of different natures, and may yet be distinguished from one another by means of their actions or developments. Many interesting questions are suggested in connection with the fact of the presence of such considerable numbers of living cells in the air. What becomes of them when drawn into the respiratory cavities of animals? Is their vitality destroyed, and, if so, how are they got rid of? Are they ever capable of undergoing any development within the organism, and do they then exert any prejudicial influence on the recipient? These and similar questions can only be answered by means of patient and extended experiment, but even such imperfect and superficial observations as the present will, I trust, serve a useful purpose in clearing away a few of the preliminary obstacles from the path of investigation.

NOTES

A SPECIAL General Meeting of the Linnean Society is to be held on Thursday, March 5, at 8 P.M., "to consider alterations in the Bye-laws of the Society;" when it is expected a full explanation will be given of the reasons which induced the Council to make the alterations recently adopted by the Society, which met with such violent opposition from a small section of the Fellows. It is understood that Mr. Bentham, who has occupied the chair of the Linnean Society for the past eleven years, will not offer himself for re-election at the ensuing anniversary. The custom of the Society requires that the next president shall be a Zoologist, but students of both branches of Biology will be glad to learn that Prof. Allman has allowed himself to be nominated. Few naturalists would bring to the office a wider, and none a more sympathetic knowledge.

MR. HIND writes to the *Times* that he has received from Prof. Winnecke, Director of the Observatory at Strasburg, the following position of a comet discovered by him in the Constellation Vulpecula on the morning of Saturday last:—February 20, at $17^h\ 16^m\ 40^s$ mean time—right ascension, $20^h\ 35^m\ 34{\cdot}2^s$; north declination, 26 deg. $0^m\ 46^s$. The diurnal motion in right ascension is 9^m increasing, and in declination 1 deg. 30^m towards the south.

PROF. ASA GRAY has been appointed to fill the Chair in the Board of Regents of the Smithsonian Institution, previously occupied by the late Prof. Agassiz.

THE Rev. Dr. Thomas William Jex-Blake, Principal of Cheltenham College, has been elected Head-Master of Rugby School, in succession to Dr. Hayman.

A BARONETCY has been conferred upon Dr. George Burrows, F.R.S., President of the Royal College of Physicians.

WE would direct the attention of Palæontologists and others who are specially interested in the Cephalopoda, to a paper by M. Munier-Chalmas, in the *Comptes Rendus* for Dec. 29, 1873, which is translated in the current number of the *Annals and Magazine of Natural History*, in which, from a study of their earliest stages, the generally accepted systematic position of the Ammonitites and Goniatites is stated to be inaccurate, they being shown to be dibranciate decapoda allied to Spirula, and not tetrabranchiata at all.

THERE are two islands named St. Paul in the ocean: one close to the Equator was visited lately by the *Challenger;* the other, south of the Cape of Good Hope, is to be visited by a French expedition under Capt. Mouchez, for observing the forthcoming transit of Venus, as we stated in our last number. The identity of name has created a singular confusion. The French administration having decided that no naturalist was needed for St. Paul, the *Challenger* having explored the island a few months since, M. Mouchez had some trouble, it is said, to get the decision reversed by the authorities. Both islands, southern and northern, are almost of the same microscopical size and equally barren. They are of volcanic formation, with no trace of vegetable earth, and consequently of vegetation.

A TELEGRAM from Melbourne, dated February 17, states that Colonel Egerton Warburton has reached Perth, in Western Australia, overland from Adelaide, having thus accomplished the object of the exploring expedition on which he left Tennant's Creek, north of Adelaide, in the centre of Australia, about twelve months ago. Colonel Warburton's explorations embrace a portion of the interior of Western Australia hitherto unknown. The distance traversed is over 1,000 miles of longitude, the expedition having been conducted by means of camels, and was fitted out by the munificent liberality of the Hon. Thomas Elder, M.L.C., and Mr. W. W. Hughes. Another expedition under Mr. Gosse, conducted with horses at the expense of the Government of South Australia, has not been so successful. Mr. Gosse, amid many difficulties caused by want of water and the barren nature of the country through which he passed, managed to reach as far as E. long. 129° 59′ in lat. 26° 32′ S., the total distance traversed irrespective of numerous turnings and windings, being not less than 600 miles. His most notable discovery was made in lat. 25° 21′, long. 131° 14′, being a hill consisting of one solid rock (fine conglomerate) or huge natural monolith two miles long, one wide, and 1,100 feet high, with a spring coming from its centre; Mr. Gosse named it "Ayres Rock." Both expeditions are highly creditable to the enterprise of South Australia, which, as our readers know, has succeeded in carrying a line of telegraphy right across the country, from Port Augusta to Port Darwin.

THE enterprise of the Australian Colonies is producing really valuable scientific results, as will be seen from the following telegram, dated Dec. 22, published in the *Brisbane Courier*, from Mr. G. Elphinstone Dalrymple, commander of the Queensland North-east Exploring Expedition:—"The coasts, harbours, inlets, navigable rivers, and creeks have been examined from latitude 18° 15′ to 15° 15′ S. The Bellenden Kerr mountain range has been successfully ascended, and found to be a complete 'razor back' of granite. Palms were found on the summit; but although the botanical discoveries were interesting, they have not borne out all that was anticipated from them; 144 miles of soundings and 371 compass cross bearings have been taken in 19 navigable rivers and creeks of which the North and South Johnstone, the Mulgrave and Russell, drain the Bellenden Kerr range; the Mossman and Daintree drain the Arthur Palmer range inside the Schnapper Island. This range is nearly as lofty as the Bellenden Kerr, and is 25 miles in length. New rivers have been discovered penetrating a jungle-clad country of thoroughly tropical character, covered with a new rich soil suitable for sugar and other tropical cultivation. The extent of this country is roughly estimated at, in the aggregate, half a million acres, thus at once placing Queensland on a par with other favoured tropical countries. Mr. Hill has collected 3,000 botanical specimens, roots, and blocks of timber; 130 shells of five genera and eight species; 42 specimen bags of soils. Mr. Johnstone has collected 30 specimens of interesting birds, insects, and reptiles; and I have obtained 93 geological specimens."

The French Society of Geography and the Commission delegated by the Syndical Chambers of Commerce of Paris have instituted a "Commission of Commercial Geography." This Commission has for its object—1. To spread in France, either by education or by publications, information relating to commercial geography; 2. To pursue the organisation or development, from an industrial and commercial point of view, of explorations in all quarters of the globe; to take part in researches relative to existing routes or to create new ones; 3. To point out the natural riches and the manufacturing processes which may be utilised by commerce and industry; 4. To inquire into all questions relating not only to the development of French colonisation, but also to the colonial systems of the various civilised nations. The Commission is divided into four sections corresponding to the above, and in the interval between the general meetings these sections hold stated *séances* for discussing questions, their decisions being submitted to the approbation of the Commission.

The Paris Jardin d'Acclimatisation has just received a flock of six magnificent male ostriches and twelve females presented to it by General Lacroix-Vaubors, who holds a high command in Algeria. All attempts to breed these birds have hitherto proved futile, but a new attempt is to be made under the sun of Provence. The six ostriches will not remain long in Paris, and are to leave soon for Hyeres, where the Acclimatisation Society possesses a large estate.

The Meteorological Society of France has decided upon holding its next Biennial Exhibition at the Palais de l'Industrie, Champs Elysées: it is to be an International one. The expenses being paid by the Government, no charge will be made for exhibiting. A special circular will be sent to the English Society this year.

The *New York Tribune* in calling attention to the unauthentic character of a story to the effect that the non-existence of the companion star of Procyon, and of all except two of the satellites of Uranus, had been determined by the new telescope at Washington, announces the first important result obtained from this instrument. The recent observations have resulted in the rediscovery of the two smallest moons of Uranus, which have been not only distinctly seen on several occasions, but have actually been measured by Prof. Newcomb and his assistant, Prof. E. L. Holden. The two larger moons of Uranus, first discovered by Sir Wm. Herschel, are well-known objects, and can be seen under favourable circumstances with any telescope of 12 in. aperture. The two smallest were first discovered by Lassell, about twenty years ago, through the fine instrument attached to his private observatory near Liverpool; but his observations were very unsatisfactory (scarcely, indeed, determining the exact number of moons), and it was not until he renewed his researches at Malta that he obtained any accurate indications. Since that time, and until this re-discovery, no one has seen these satellites, and their detection and accurate observation through the Washington instrument is gratifying evidence of its superior power.

Mrs. Mary Treat publishes in the *American Naturalist* for December 1873 a remarkable contribution to our knowledge of the sensitiveness of the leaves of the sundew, her experiments being chiefly made on the large American species *Drosera filiformis*, the leaves of which capture and kill moths and butterflies two inches across. Her observations are in accordance with those already recorded on English species, that the motion of the glands is excited only by organic substances, or if for a very short time by mineral substances, that the excitement passes off almost immediately. The most astonishing of her observations is, however, that when living flies are pinned at a distance of half an inch from the apex of the leaf, the leaf actually bends towards the insect until the glands reach it and suck its juices. In the *Naturalist* for January is an account of Roth's observations on the irritability of the sundew, made nearly a century ago.

We have before us the first number of what seems to us likely to be a most useful work—"Insects of the Garden; their habits," &c., by Dr. A. S. Packard. The present number contains 32 pp. with woodcuts and a coloured plate, and is published at 25 cents. It forms part of a work called "Half hours with Insects," to be completed in 12 parts.

An advance sheet of the forthcoming number of Petermann's *Mittheilungen* contains an official account of the voyage of Count Wiltschek in the summer of 1872 to Spitzbergen and Novaya Zemlya in the yacht *Isbjörn*, the chief object of which was to plant a provision depôt in the Arctic Sea for the Austro-Hungarian expedition under Weyprecht and Payer in the *Tegethoff*. The account contains some valuable observations on the ocean-currents, temperature, weather, wind, &c., of the region, and the geology of Novaya Zemlya; collections of the fauna and flora of that island were made, and photographic views were taken. Nothing is known at present of the Austro-Hungarian expedition in the *Tegethoff*, though it is probable that she may be wintering somewhere on the coast of Siberia.

The Government of Peru have for some years been expending vast sums of money in exploring the little known portions of Peru which lie to the west of the Andes, and Señor Raimondi, a scientific man of the highest character, has, in the service of the Government, been also exploring the remote valleys between the Cordilleras, and at the head waters of many of the rivers which flow down the northern slopes to the eastern plains, a work in which he has been engaged for twenty years. The announcement is now made that the labours of Señor Raimondi are to be utilised in the publication, by the Government, of a magnificent illustrated work, which is to embrace a narrative of his explorations, and the result of all his researches upon the geography, natural history and climate of Peru.

In a "Note Additionelle," by Mr. Albert Lancaster, of the Belgian Academy, to Mr. W. T. Brigham's memoir on "Volcanic Manifestations in New England, 1638—1870," published by the Boston Society of Natural History, the author records a number of earthquakes omitted in Mr. Brigham's memoir. Taking all the recorded earthquakes in New England during the last three centuries, the author finds that ·2 occurred yearly during the seventeenth century, 1·2 during the eighteenth, and 2·0 during the nineteenth, though on account of the imperfect data of the seventeenth and eighteenth centuries, he thinks that 2·0 per annum may be taken as the average annual number of earthquake phenomena in New England. If the number of earthquakes during the three centuries be examined in reference to the months in which they occurred, it will be found that there are two distinct maxima and minima, both showing an equality almost to a unit; the former fall in February and November, the latter in April and September, and they are to each other as 3·6 : 1. Dividing the number of earthquakes according to the seasons in which they occurred, it is found that eighty-seven occurred in winter, forty-three in spring, forty-three in summer, and ninety-one in autumn. Enough is not yet known of the geological constitution of New England to enable us to explain these remarkable results, though it is hoped that the researches at present carried on by the U.S. geological officials may ere long enable us to do so.

The existence of gigantic Cephalopoda in American waters has long been suspected, and at last a large specimen of a "squid," or sepia, has been captured and preserved. The measurements, as given by the Rev. M. Harvey, of St. John's, Newfoundland, are, length of body, 7 ft.; circumference, 5 ft.;

length of two tentacular arms, 24 ft. each; eight pedal appendages, 6 ft. in length, and 9 in. in circumference nearest the head; the sucking-discs are denticulated, and in some instances measure $1\frac{1}{4}$ in. in diameter. This individual has been preserved, and its measurements are therefore authentic; but still larger specimens are believed to exist, and an account is given of an encounter between some fishermen and a huge creature which, on being struck by them, attacked their boat by twining its arms round the vessel. Two of the arms were cut off by a fisherman, when the squid moved off, ejecting a large quantity of inky fluid to cover its retreat. A portion of one of these arms, measuring 19 ft., has been preserved, but it is said that 6 ft. of it were destroyed, while the fishers estimate that they left 10 ft. more on the body of the squid. This would bring its length to 35 ft. It is to be hoped that more care will in future be taken to prevent the mutilation of specimens; and the capture of the first-mentioned one will, no doubt, excite the fishermen and others to greater care and exertions in looking out for still larger examples. The first squid was caught in Logy Bay, Newfoundland. The encounter with the second took place off Portugal Cove, Conception Bay, about 9 miles from St. John's.

AT a recent meeting of the Essex Institute (Salem, Mass.), Mr. Byron Groce of Peabody read a paper on "The Study of Natural History in Schools," in which he advocated its introduction by substituting it for some of the less useful studies now pursued. He also gave an account of the method he had followed in the High School of Peabody, stating that during the summer he took his school into the woods and fields for a half day each week, taught the scholars to collect specimens and preserve them properly; then had the specimens arranged in the school cabinet, and on unpleasant days in the winter they were used for instruction. In this way a lively interest had been created in the school, and a Natural History Club had been formed among the scholars for the purpose of carrying on the study.

A NEW illustrated weekly newspaper is announced for first appearance on March 7. The title is the *Pictorial World*. We trust the projectors will be wise enough—to take the word in its largest sense—to let its readers know something of what is being done in the world of Science.

WE have received a map (published by the U.S. Geological Survey) of the sources of the Snake River, with its tributaries, together with portions of the head waters of the Madison and Yellowstone, from surveys and observations of the Snake River Expedition, by G. R. Bechler, Chief Topographer, and James Stevenson, Director. The scale is five miles to an inch, and all the remarkable features of the extensive district, which includes the Yellowstone National Park, and the nature and products of the ground, are clearly indicated.

WE have received the third volume, for 1873, and the commencement of the fourth volume of the "Procès-verbaux des Séances de la Société Malacologique de Belgique," showing the activity with which this department of Natural History is pursued in Belgium.

THE additions to the Zoological Society's Gardens during the past week include a Crested Agouti (*Dasyprocta cristata*), from Mexico, presented by Mr. C. H. M. de Lichtacbel; a Pennant's Parakeet (*Platycercus pennanti*), and a Cockateel (*Calopsitta novæ-hollandiæ*), from Australia, presented by Dr. H. Wheeler; a Common Gull (*Larus canus*), British, presented by Mr. W. K. Stanley; a Malayan Hornbill (*Buceros malayanus*), from Malacca, purchased; and a hybrid Pheasant (between *Thaumalia amherstiæ* and *T. picta*), received in exchange.

SCIENTIFIC SERIALS

Justus Liebig's Annalen der Chemie u. Pharmacie, Band 170, Heft 1 und 2. This number contains the following papers:—On the chlorides and oxy-chlorides of sulphur, by A. Michaelis. The author describes the compound SCl_4 and other chlorides, also an oxy-chloride of the formula $S_2O_5Cl_2$. He gives tables and curves showing the dissociation of SCl_4 which is very rapid between $-20°$ when 100 per cent. of that body exists and $+6°\cdot2$ when only 2·43 per cent. exists as SCl_4, the rest consisting of SCl_2 and chlorine. SCl_2 dissociates much less rapidly, 5·44 per cent. existing at a temperature of $+120°$. Researches on the nature and constitution of gallic acid, by H. Schiff. A correction of the formula of carbazolin, by C. Gräbe.—On capronic acid contained in the crude butyric acid of fermentation, by A. Lieben—On the salts of capronic acid derived from fermentation, by F. Kottal.—On a condensation product of oxybenzoic acid, by L. Barth and C. Senhofer. The author's obtained a body of the formula $C_{14}H_8O_4$; two of the hydrogens of this formula are replaceable by metals. The Ba Ca, K and Na salts thus formed are described. On treating the original body with zinc, anthracene was obtained. They propose to call this body Anthraflavon; it is useles as a dye-stuff.—On phenol-trisulphuric acid, by C. Senhofer. The acid is prepared by acting on sulphuric acid with phosphoric anhydride in the presence of phenol; it is a tribasic acid of the formula $C_6H_6S_3O_{10}$ crystallising with $3\frac{1}{2}$ molecules of water. Several of its salts are described.—On orthoxylol prepared from liquid brom-toluol, by P. Jannasch and H. Hübner.—On the action of ozone on carburetted hydrogen, by A. Houzeau and A Renard. This is a translation from a paper in the *Comptes Rendus*, vol. lxxvi., 572.—On dichlorglycide, by A. Claus. This body is prepared by the action of potassic hydrate on trichlorhydrin. On the action of potassic cyanide on dichlorglycide, by the same author.—On œnanthylic acid and normal heptyl alcohol, by Harry Grimshaw and C. Schorlemmer.—On trimethyl acetic acid, by A. Butlerow.—On the dichlor propionic ether from glyceric acid, by Messrs. Werigo and Werner.—Contributions to our knowledge of citric acid; and On baric citraconate, by H. Kämmerer.—On dissociation, by A. Horstmann.—The number concludes with a short reply to Butlerow's paper on trimethyl carbinol, by E. Linnemann.

Bulletin de la Société Imperiale des Naturalistes de Moscou. No. 2. 1873.—This number commences with a paper by Dr. Koch on malformations in the embryos of species of salmon and Coregonus; the various monstrosities being treated under the headings of (1) Dicephaly; (2) Diplomyelia (duplicity of spinal cord, total or partial; (3) Divergences of body from its long axis; (4) Defects in organs of locomotion; (5) Anomalies in the vegetative sphere; (6) Defects in organs of sense. As to the disputed point how double monsters arise, Dr. Koch finds confirmation of I. Müller's view, according to which they are produced through union of two organised embryos arising from an imperfect fission. He also asserts that double monsters, where both bodies are formed alike, never live after leaving the egg, and when the yolk has been absorbed; other monsters may, if the form permits of food being procured. From experiments made on production of monsters, it seemed well established, that unfavourable conditions, such as shaking, were peculiarly apt to cause them; even double formations, but only of a certain kind, viz. *Diplomyelia partialis*, not *D. totalis*. The influence of temperature was also seen in the fact, that, with embryos in these unfavourable conditions, a difference of three degrees R. (above the normal cold temperature), made a difference of twelve days in the time of development, which was to this extent retarded. The paper is accompanied with numerous illustrations.—M. Wolkenstein continues his account of anthropological researches on the ancient cemeteries of Waldai, named "Jalnikis;" giving here detailed measurements of the skeletons found in these peculiar tombs.—M. Becker describes a journey he made in 1872 to several places in the neighbourhood of the Caspian and in South Daghestan; apppending a list of plants and animals found there.—M. Truntschold furnishes some measurements of *Elasmotherium sibericum*; M. Motschoulsky a list of new species of Coleoptera; and there are one or two notes, in Russ, on botanical subjects.

Astronomische Nachrichten, No. 1973. In this number Dr. Stein gives an account of an apparatus for astronomical photography, with which the negatives are taken without the use of a dark room or tent, and if useful in practice, it justly deserves credit. It consists practically of a sort of flat box of glass, one

side of which is the collodionised plate which fits water-tight against the other sides by means of india-rubber packing. There is a tube passing into this box through which first the ordinary silver solution is poured, and then by laying the collodionised plate downwards it is covered by the solution and sensitised; this is then drawn off, and the box, which is contained in a suitable holder, placed on the telescope and exposed by drawing away the non-actinic glass cover in front. After exposure the coloured glass is replaced, the box removed and developed by pouring in the solution in the same manner as the silver, in the meantime watching the plate through the coloured glass; the washing is then proceeded with in the same manner.—Dr. Stein proposes to use this method for photographing the transit of Venus.—Prof. Schmidt contributes a paper on the rotation of Jupiter, in which he discusses all the old observations of Cassini and others. From his list we gain that these observers differed to the amount of 6^m, the minimum being $9^h\ 50^m$, and the maximum $9^h\ 56^m$. From Prof. Schmidt's observations in 1873, he obtains a period of $9^h\ 56^m\ 7{\cdot}2^s$.

Archives des Sciences Physiques et Naturelles, Dec. 15, 1873.—In this number a short opening notice of M. de la Rive is followed by an article by M. Wiedemann, being an extract from his recent work on elliptic polarisation of light, and its relations with the superficial colours of bodies. The author shows that superficial colours change considerably with the nature (indices of refraction) of the substances in contact with which they are produced; and colours the most strongly reflected present generally the most intense elliptic polarisation, provided the reflection occurs in air or in vacuo. The principal angles of incidence undergo the most rapid modifications for wave-lengths corresponding nearly to the bands of absorption. M. Wiedemann's work elucidates the connection between the phenomena of bodies with superficial colours and the principal angles of incidence and relations of amplitude.—Dr. Hermann Müller's recent interesting work on fertilisation of flowers by insects is reviewed in a paper which gives a succinct *résumé* of the principal results.—M. Plantamour furnishes an account of the proceedings of the Meteorological Congress held at Vienna in 1873, and the circumstances which led to it.—There is also a note on the early development of Geryonides, by M. Fol; and this is followed by the usual scientific summary.

Ocean Highways, February.—About one-third of this number is occupied by a paper by Captain R. F. Burton, describing "Two Trips on the Gold Coast," the first being to the Beauleh Gardens and Agimanti Hills, and the second along the shore to the Volta River. The paper, which is written in Captain Burton's characteristic and attractive style, and illustrated by two maps, is full of information, and will no doubt prove interesting to many at the present time. An article on the Bengal Famine recounts the principal Indian famines from 1661 to the present time, and shows how much could be done to foresee and obviate the consequences of famine by a more scientific investigation of the laws which regulate meteorological phenomena. The article is accompanied by a map showing the extent of the famine districts. In a short article on "Wyche's Land," called by the Germans after King Karl of Wurtemburg, it is shown satisfactorily, we think, that the honour of the discovery, by right, belongs to Edge's expedition in 1617, and that the name then imposed should remain unchanged. Some interesting details are given of Richard Wyche or Wiche, the London merchant, who did much to encourage early discovery. Other articles are on "European Emigration to the Argentine Republic," and on the "Provindah Trade," or trade of the Lohani merchants, who are the channels of communication between India and Central Asia.

SOCIETIES AND ACADEMIES

Royal Society, Feb. 12.—"On the Division of Sound by a layer of flame or heated gas, into a reflected and a transmitted portion," by John Cottrell, Assistant in the Physical Laboratory of the Royal Institution; communicated by Prof. Tyndall, F.R.S.

A vibrating bell contained in a padded box was directed so as to propagate a sound-wave through a tin tube and its action rendered manifest by its causing a sensitive flame placed at a distance in the direction of the sound-wave to become violently agitated.

The invisible heated layer immediately above the luminous portion of an ignited coal-gas flame issuing from an ordinary bat's-wing burner was allowed to stream upwards across the end of the tin tube, from which the sound-wave issues. A portion of the sound-wave, issuing from the latter, was reflected at the limiting surfaces of the heated layer; and a part being transmitted through it, was now only competent to slightly agitate the sensitive flame.

The heated layer was then placed at such an angle that the reflected portion of the sound-wave was sent through a second tin tube (of the same dimensions as the above), and its action rendered visible by its causing a second sensitive flame placed at the end of the tube to become violently affected. This action continued so long as the heated layer intervened; but upon its withdrawal the first-mentioned sensitive flame, receiving the whole of the direct pulse, became again violently agitated, and at the same moment the second sensitive flame, ceasing to be affected, resumed its former tranquillity.

Feb. 19.—"On the Number of Figures in the Period of the Reciprocal of every Prime Number below 17,000," by William Shanks, Houghton-le-Spring, Durham.

"On an Instrument for the Composition of the Harmonic Curves," by E. A. Donkin, Fellow of Exeter College, Oxford.

"On the Absorption of Carbonic Acid by Saline Solutions," by J. Y. Buchanan, chemist on board H.M.S. *Challenger*.

Linnean Society, Feb. 19.—J. Gwyn Jeffreys in the chair. —The chairman announced that a Special General Meeting of the Society would be held on Thursday, March 5, at 8 P.M., to consider alterations in the Bye-laws of the Society." The following papers were read:—Systematic list of the Spiders at present known to inhabit Great Britain and Ireland, by the Rev. O. P. Cambridge.—Some observations on the vegetable productions and rural economy of the province of Baghdad, by Surgeon-major W. H. Colvill.—Note on the Bracts of Crucifers, by Dr. M. T. Masters.

Zoological Society, Feb. 17.—George Busk, F.R.S. vice-president, in the chair. Mr. Busk exhibited some skulls of the tiger and leopard from China, procured by Mr. R. Swinhoe, and showed that those from the northern and southern provinces did not appear to be specifically distinct.—A communication was read from Mr. L. Taczanowski, Conservator of the Museum of Warsaw, containing the descriptions of twenty-four new birds, obtained by Mr. Constantine Jelski in Central Peru. Amongst these was a new Cotingine form, proposed to be called *Dolyornis sclateri*, and four new humming-birds named respectively *Metallura hedvigæ*, *Helianthea dichroura*, *Eriocnemis sapphiropygia* and *Lampraster branickii*.—A communication was read from Sir Victor Brooke, Bart., describing a new species of Gazelle, founded on two specimens living in the Society's Menagerie, which he proposed to call *Gazella muscatensis*.—A communication was read from Dr. T. Schomburgh, Director of the Botanic Gardens, Adelaide, containing an account of the habits of the Australian Coote (*Fulica australis*) as observed in the Gardens under his charge.—Mr. E. Ward exhibited the head of a supposed new species of Wild Sheep, from Ladak, which he proposed to name *Ovis brookei*, after Sir Victor Brooke.—Dr. J. E. Gray, F.R.S., communicated some notes on the Crocodile of Madagascar, which he proposed to distinguish from *Crocodilus vulgaris* of Continental Africa, and to call *Crocodilus madagascariensis*.—A communication was read from Mr. W. N. Lockington, of Humboldt County, California, containing some notes on the mammals and birds met with in that part of the State of California.

Mathematical Society, Feb. 12.—Dr. Hirst, F.R.S., president, in the chair.—Prof. Clifford gave in some detail a statement of the views advanced in his paper on the foundations of dynamics.—A discussion ensued, in which Messrs. Wilkinson, Moulton, Cayley, Roberts, and G. H. Lewes took part.—Mr. Clifford having answered questions and replied to objections, proceeded next to give an account of a paper on the free motion of a solid in elliptic space.—Owing to the lateness of the hour a paper by Mr. C. J. Monro, entitled "Note on the Inversion of Bernoulli's Theorem in Probabilities," was taken as read. Under the name of Bernoulli's Theorem are comprehended two theorems which, with a little licence, we may distinguish as the deductive and the inductive. The deductive theorem assumes the constant probability p of a given result on a single trial, and determines the probability P that on m trials the result will be produced from $mp - l$ to $mp + l$ times, or from $x - l$ to $x + l$, if x is the greatest integer in $mp + p$. The inductive theorem

assumes that the given result is produced mp times on m trials, which give a constant facility for its production (that is, are made under definable circumstances, which, if defined, would give a constant probability for the same), and determines P′, the probability that this facility lies between $p \pm \frac{l}{m}$. In the deductive theorem it is supposed that $\frac{1}{m}$ may be neglected; and in the inductive $\frac{1}{\sqrt{m}}$. (The author here refers to Mr. Todhunter's "History," p. 555, and to Mr. De Morgan's treatise in the "Enc. Metr.," § 77.) The object of the paper was to show, first that there is an oversight in Laplace's statement of the inversion (see Todhr., § 997), the correction of which removes the inconsistency of the results; and secondly, that upon the hypothesis of equally probable values within equal ranges, the inversion is so far legitimate that either theorem may be inferred from the other with little calculation, and in particular without the approximate evaluation of a general integral, and accordingly that the two solutions are identical in principle.

Chemical Society, Feb. 19.—Prof. Odling, F.R.S., president, in the chair.—Mr. James Bell delivered his lecture "On the Detection and Estimation of Adulteration in Articles of Food and Drink." The lecturer, after some preliminary remarks on the fiscal regulations with regard to adulteration, began with a description of the microscopic appearance of the various kinds of starch, as many of them, from their cheapness, are largely employed for the purposes of adulteration; he then considered the characters of pure coffee and of the various substances used to adulterate it, pointing out the most convenient methods for their detection. Tea, pepper, and mustard, were afterwards treated of in the same way. Owing to want of time, Mr. Bell was unable to complete the lecture, so that the adulteration of cocoa, tobacco, and beer was not touched upon. This admirable and instructive lecture was copiously illustrated by the most beautifully executed drawings of the structure of the various substances as exhibited under the microscope. After the lecture many of the Fellows availed themselves of the opportunity afforded them of looking over the extensive collection of microscopic preparations connected with the subject.

Entomological Society, Feb. 2.—Mr. J. W. Dunning, vice-president, in the chair.—Mr. Müller exhibited a blind Myriapod and others found in a limestone cave in the Jurassian Mountains; he believed them to be the first found in the caves of Switzerland.—Mr. Kirby exhibited *Lycæna phœbe* from Australia, which had been described by the Rev. R. P. Murray.—Specimens were exhibited of *Monohammus leuconotus*, a Longicorn beetle which was very destructive to the coffee plantations in Natal. The only remedy that appeared to have been tried was the application of Stockholm tar to the roots of the trees; but handpicking was suggested on the first appearance of the insect in the imago state. This was the practice usually adopted on the continent of Europe with regard to *Melolontha*. Also it was desirable to protect the insectivorous birds, which were frequently shot for the sake of their plumage.—Mr. Butler forwarded some corrections of the synonymy with regard to *Apatura herse* and *A. lycaon* of Scudder and Riley, which were equivalent to *A. clyton* and *A. celtis*, Boisduval; whereas *A. herse* and *A. lycaon*, Fabricius, were sexes of one species = *A. alicia*, Edwards.—A paper was communicated by Mr. Herbert Druce, entitled "Descriptions of fifteen species of Diurnal Lepidoptera, chiefly from South America."

Meteorological Society, February 18.—The papers read were:—"General Remarks on the West Indian Cyclones, particularly those from the 9th to the 21st Sept., 1872," by Mr. F. H. Jahncke, harbour-master of St. Thomas; "New Forms of Alcohol Thermometers," and "An Improved Vacuum Solar Radiation Thermometer," both by Mr. James J. Hicks; and "Note on a Waterspout which burst on the Mountain of Ben Resipol, in Argyleshire, in August, 1873," by Mr. Robert H. Scott, F.R.S. A very interesting discussion followed the reading of each paper. That upon Mr. Jahncke's led to expressions of opinion on the origin, form, tracks, and general characteristics of West Indian Hurricanes, and of the best means of improving and increasing the records of weather phenomena in those parts. The special feature in Mr. Hicks's second paper was the application of an electric current as a test for the perfection of the vacuum, which principle was very beautifully illustrated by experiments.

EDINBURGH

Scottish Meteorological Society, Jan. 29.—Mr. M. Home, of Wedderburn, in the chair.—From the report of the council it appears that two new stations, viz., Broadlands, Peebleshire, and Ochtertyre, Crieff, have been added to the society's stations, and that Kettisis and Cairndow have ceased to be stations. Thus the number of stations in connection with the society is the same as at last meeting, viz., 92 in Scotland, 5 in England, 4 on the Continent, 2 in Iceland, 1 in Faro, and 1 in South America. Observations have also been begun to be made for the society at Melstad, in the north of Iceland, and at Fairlie Plains, Paroo River, near the northern watershed of the River Darling, Australia. The council had had offers of many more stations, some in most eligible districts; but the establishment of these would have entailed additional expenditure which the society's funds would not justify. Teachers of several schools had also made known their wish to observe for the society, provided they were furnished with instruments, at the same time proposing to introduce into their schools some instruction in meteorology. The council, however, had been obliged to decline these applications for want of funds. The membership of the society is at present 560. In room of the three members of council who retired, Prof. Alexander Dickson, Dr. J. Robson Scott, and Mr. George Hope, of Broadlands, were elected.—An application has been made to the council by Mr. Colin McVean on behalf of the Government of Japan for advice regarding the establishment of a system of meteorological observations in Japan. In answer to this application, the council has forwarded a memorandum regarding suitable instruments, their position, hours of observation, the establishment of a central observatory, inspection of stations, publications, and special observations of storms.—Mr. Buchan submitted a second report of the committee appointed to carry out the Marquis of Tweeddale's proposal to investigate the relations of the herring-fisheries to meteorology. The committee had, with the assistance of the Hon. Bouverie F. Primrose, of the Fishery Board, obtained complete returns of the daily catch of herrings and state of the weather from all the fishing districts of Scotland during the past season. Thirty-five weather maps at 9 P.M., specially constructed with reference to this question, and showing the number of boats out fishing in each district each day and the average catch of each boat, were shown to the meeting. Some interesting relations between the catches of the different districts and the prevailing weather were pointed out; and as these were in general accordance with the results stated in the first report, presented in July last, it is highly probable that when the statistics of three or four years' fishings similar to the very satisfactory returns of the past year have been collected, valuable conclusions will be arrived at.—Mr. Thomas Stevenson, in bringing before the meeting a proposed inquiry regarding storms, remarked that the barometric gradients hitherto ascertained having been deduced from readings at stations many miles apart, necessarily could not give more than a rough approximative gradient. What is wanted in order to get a formula for computing the velocity of the wind due to a given gradient is, as he (Mr. Stevenson) suggested in NATURE, vol. ix. p. 103, to have a string of stations at short distances apart. It is now proposed to establish such storm stations, arranged in lines radiating from Edinburgh for a distance of about twenty miles, and it is believed that in addition to the existing stations of the Scottish Society many farmers and others possess good barometers, which could be compared with the society's standard. It is proposed that observations of the instruments and of the weather should be limited to the periods during which storms last, and a special schedule for the observations had been prepared.—Mr. Buchan gave an account of the proceedings of the Meteorological Congress held at Vienna in September last, to which he and Mr. Scott, of the Meteorological Office, London, had been sent as delegates from the British Government.

Geological Society, Feb. 12.—A paper was read by Mr. John Horne, of the Geological Survey of Scotland, on "The Geology of the Isle of Man." The chief points of interest in the paper were the correlation of the red sandstones and Breccias with the Lower Carboniferous series of Scotland, and the proofs adduced that the volcanic rocks were probably on the same horizon as the upper limestone shales of England. Detailed evidence was given to show that the Isle was glaciated by a confluent ice-sheet from the north-west of England, south of Scotland, and the north-east of Ireland. The two submarine

hollows lying between the Portpatrick coast and the north-east of Ireland, and between Anglesea and the coast south of Dublin, were attributed to the increased erosive action of the ice-sheets due to the narrowness of the channel at these points.—Mr. Andrew Taylor gave a description of the course of the River Almond, near Edinburgh, and stated that that river followed, at various places, which he specified, lines of "faults."

MANCHESTER

Literary and Philosophical Society, Feb. 3—*Physical and Mathematical Section*.—Alfred Brothers, F.R.A.S., President of the Section, in the chair.—"On the Theory of the Tides," by David Winstanley.

Feb. 10.—R. A. Smith, F.R.S., V.P., in the chair.—"The Northern Range of the Basques," by W. Boyd Dawkins, F.R.S. The northern extension of the Basque race from their present boundary, in ancient times, is demonstrated by the convergent testimony of history, ethnology, and the researches into caves and tombs. In the Iberian peninsula the Basque populations (Vascones) of the west are defined from the Celtic of the east by the Celtiberi inhabiting modern Castille. In Cæsar's time, the Aquitani were surrounded on every side, except the south, by the Celtæ, extending as far north as the Seine, as far to the east as Switzerland and the plains of Lombardy, and southwards, through the valley of the Rhone and the region of the Volscæ, over the Eastern Pyrenees into Spain. The district round the Phocæan colony of Marseilles was inhabited by Ligurian tribes, who held the region between the river Po and the Gulf of Genoa, as far as the western boundary of Etruria, and who probably extended to the west along the coast of Southern Gaul as far as the Pyrenees. The ancient population of Sardinia is stated by Pausanias to be of Libyan extraction, while that of Corsica is described by Seneca as Ligurian and Iberian. The Basques, or Ligurians, are the oldest inhabitants, in their respective districts, known to the historian; while the Celts appear as invaders. We may be tolerably certain that the Basques held France and Spain before the invasion of the Celts, and that the non-Aryan peoples were cut asunder, and certain parts of them left—Ligurians, Sikani, and in part Sardinians and Corsicans—as ethnological islands, marking, so to speak, an ancient Basque non-Aryan continent which had been submerged by the Celtic populations advancing steadily westwards. The Celtic and Belgic invasion of Gaul repeated itself, as might be expected, in Britain. Just as the Celts pushed back the Iberian population of Gaul as far south as Aquitania, and swept round it into Spain, so they crossed over the Channel and overran the greater portion of Britain, until the Silures, identified by Tacitus with the Iberians, were left only in those fastnesses that formed subsequently a bulwark for the Brit-Welsh against the English invaders. The Basque non-Aryan blood is still to be traced in the dark-haired, black-eyed, small, oval-featured peoples in our own country in the region of the Silures, where the hills have afforded shelter to the Basque populations from the invaders. The small swarthy Welshman of Denbighshire is, in every respect, except dress and language, identical with the Basque peasant of the Western Pyrenees, at Bagnéres de Bigorre. The small dark-haired people of Ireland, and especially those to the west of the Shannon, according to Dr. Thurnam and Professor Huxley, are also of Iberian derivation, and, singularly enough, there is a legendary connection between that island and Spain. The human remains from the chambered tombs as well as the river-beds prove that the non-Aryan population spread over the whole of Ireland as well as the whole of Britain. The evidence offered by an appeal to history and ethnology, as to the former northern extent of the Basque peoples, is confirmed by an examination of the human remains in the Neolithic caves and tombs, scattered throughout the area under consideration. The discoveries in the caves of Gibraltar and of the Spanish mainland prove that a small long-headed race, with delicate features and orthognathic profile identical with the Basques who buried their dead in the modern cemetery of Guipuscoa, ranged throughout the Peninsula, using with indifference caves and chambered tumuli for their tombs. And on the same grounds their former range through France, Britain, and Ireland is demonstrated, and as far to the east as Belgium. At the present time the Basque blood asserts itself in the physique of certain isolated populations, and within the historic period is demonstrated to have been more strongly defined, and to have occupied larger areas, and lastly in the prehistoric period to have formed one continuous race from the Pillars of Hercules, as far north as Scotland, and as far to the east as Belgium.

NEW HAVEN, U.S.

Connecticut Academy, Dec. 17, 1873.—Prof. Lyman, president, in the chair.—Prof. Marsh, of Yale College, gave an account of the explorations of his party in the Rocky Mountains and on the Pacific Coast during the past season. The first explorations this year were made in the Pliocene deposits near the Niobrara River. Owing to hostile Indians, the explorations of the party here were attended with much difficulty and danger, but were on the whole quite successful. Many new animals were discovered, and ample material secured for a full investigation of those previously known from that region. A second expedition was made in August from Fort Bridger, Wyoming, and large collections of Eocene fossil vertebrates were obtained, especially of the *Dinocerata*, *Quadrumana*, and *Chiroptera*, which had first been brought to light by the researches of the party in previous years. A third trip was made in September to the tertiary beds of Idaho and Oregon, where some interesting discoveries were made.

PARIS

Academy of Sciences, Feb. 16.—M. Bertrand in the chair.—The following papers were read:—On the acid waters which flow from the volcanoes of the Cordilleras, by M. Boussingault.—On a mechanical equation corresponding to the equation $\int \frac{dQ}{T} = 0$, by M. R. Clausius. This was a paper relating to those of M. A. Ledieu on the same subject which have recently been read.—Report on a memoir, by M. Marey, on the point of action of a wing on the air, M. Tresca, reporter.—Experiments to determine whether all the vascular nerves have their focus of origin and their vaso-motor centre in the rachidian bulb, by M. A. Vulpian.—New topographical chart of Mont Blanc on a scale of $\frac{1}{40,000}$, by M. E. Viollet-Leduc.—M. Ad. Chatin advanced his paper On androgenesis compared with organogenesis another stage.—On the action of soft waters on metallic lead, by MM. Mayençon and Bergeret. Electrolysis was used by the authors to detect the lead, as they considered sulphuretted hydrogen not sufficiently delicate. They found galena slightly soluble in water by long boiling.—On the preservation of wood by means of cupric sulphate, by M. Boucherie.—Facts illustrating the history of yeast, by M. P. Schutzenberger.—On a transformation of Taylor's formula, by M. Jourgon.—On a method of determining vapour densities, by M. Croullebois. This method is a modification of that which depends on observing the tension of the vapour in a barometer tube.—Observations on the efflorescence of the two hydrates of sodic sulphates, by Dr. L. C. de Coppet. This was an answer to a late paper by M. Gernez.—On the "antifermentescible" and antiputrid properties of solutions of chloral hydrate, by MM. Dujardin-Beaumetz and Hirne.—On the method of respiration in certain fish having a labyrinthiform pharynx, by M. Carbonnier.—On the fossils brought from Cape Verde Islands by M. de Cessac, by M. P. Fischer.—On the movements of the chlorophyll in the *Selaginaceæ*, by M. Ed. Prillieux.—On the relations between thermo-electric properties and crystalline form, by M. C. Friedel.—On a method of quickly re-forming vineyards threatened by phylloxera by the introduction of American vines, by M. H. Bouschet.—On anesthesia produced by the injection of chloral, by M. Oré.

CONTENTS

THURSDAY, MARCH 5, 1874

PROFESSOR HUXLEY AT ABERDEEN

THE Address just given by the Lord Rector of Aberdeen University, and published *in extenso* in the March number of the *Contemporary Review*, is second in importance to none of the similar utterances which have been heard of late years. It bears in every line the stamp of a master mind. The many topics touched on, the apparent diversity of which has alarmed the shallow critic of the *Times*, are all grouped round one central idea—the advancement of Science; and there is not only a splendid unity throughout the Address, and no "uncertain sound," which, coming as it does from a Royal Commissioner charged with a special survey of our scientific needs, as well as a Lord Rector, may well fill us with confidence for his advocacy, even if one despairs of much improvement being effected in the lifetime of the present generation. It is indeed to be feared, as Mr. Huxley himself anticipates, that on many points he will be "The Rector who was always beaten;" if so, it is none the less certain that his defeats will become "victories in the hands of his successors."

It is especially fitting that the Address, dealing, as it did by its title, with "Universities: Actual and Ideal," should have been delivered in connection with one of the Scotch Universities, which, in regard to scientific research and teaching, rank higher than the older English Universities, given up in the main to "elementary teaching of youths under twenty," as the ideal University must take rank above them. We cannot too much thank Prof. Huxley for bringing out this point sharply, and quoting Mr. Mark Pattison to intensify it, all the more because the *Times* has taken hold of another sentence of the address, to point out the importance of a "pause" in the Reforms at Oxford and Cambridge, as if things were moving too fast! Surely the older English Universities may at least approach the level of the Scotch Universities, to say nothing of the French and German ones, in the matter of the higher teaching and of research before this "pause" is insisted on?

And, more than this, we conceive it to be possible that the present Government may not treat the Report of the Commission appointed to inquire into the Revenues of the Colleges at Oxford and Cambridge as mere waste paper. It has frequently been roundly asserted that the political distinctions between Liberals and Conservatives by no means represent the line of demarcation between those most and least anxious for University reforms. However this may be, it is well known that one of the most enlightened and far-seeing among University reformers, so far as the highest functions of a University are concerned, is a member of the present Government. Let us hope, therefore, that the magnitude of the pause may have been exaggerated; that the Heads after all may not oversleep themselves, that the last of Endowment may be even as the first, Endowment being, according to Professor Huxley, a foreign element,

"Which silently dropped into the soil of Universities like the grain of mustard-seed in the parable; and, like that grain, grew into a tree in whose branches a whole aviary of fowls took shelter. . . . . It differed from the preceding, in its original design to serve as a prop to the young plant, not to be a parasite upon it. The charitable and the humane, blessed with wealth, were very early penetrated by the misery of the poor student. And the wise saw that intellectual ability is not so common or so unimportant a gift that it should be allowed to run to waste upon mere handicrafts and chares. The man who was a blessing to his contemporaries, but who so often has been converted into a curse, by the blind adherence of his posterity to the letter, rather than to the spirit, of his wishes—I mean the 'pious founder'—gave money and lands, that the student who was rich in brain and poor in all else might be taken from the plough or from the stithy, and enabled to devote himself to the higher service of mankind; and built colleges and halls in which he might be not only housed and fed, but taught.

"The colleges were very generally placed in strict subordination to the University by their founders; but, in many cases, their endowment, consisting of land, has undergone an 'unearned increment,' which has given these societies a continually increasing weight and importance as against the unendowed, or fixedly endowed, University. In Pharaoh's dream the seven lean kine ate up the seven fat ones. In the reality of historical fact, the fat Colleges have eaten up the lean Universities."

We have already, in NATURE, referred to Prof. Huxley's suggested reforms in respect to the Medical Curriculum, and we may therefore pass lightly over this part of his Address, expressing a hope, however, that his reference to this subject at length may be indicative that it will be considered by the Commission of which he is so distinguished a member.

The Lord Rector points out that while he would drop Zoology and Botany in the Medical Curriculum, he would make them part of the Arts Curriculum; and after remarking that the Faculties of Theology, Law, and Medicine are technical schools, intended to equip men who have received general culture with the special knowledge which is needed for the proper performance of the duties of clergymen, lawyers, and medical practitioners, he adds,—

"I have no sort of doubt that, in view of the relation of Physical Science to the practical life of the present day, it has the same right as Theology, Law, and Medicine, to a Faculty of its own in which men shall be trained to be professional men of science. It may be doubted whether Universities are the places for technical schools of Engineering, or Applied Chemistry, or Agriculture. But there can surely be little question that instruction in the branches of Science which lie at the foundation of these Arts, of a far more advanced and special character than could, with any propriety, be included in the ordinary Arts Curriculum, ought to be obtainable by means of a duly organised Faculty of Science in every University.

"The establishment of such a Faculty would have the additional advantage of providing, in some measure, for one of the greatest wants of our time and country. I mean the proper support and encouragement of original research."

This at once brings us to what we consider by far the most important part of the Address, the Lord Rector's opinions on the endowment of unremunerative research:—

"The other day, an emphatic friend of mine committed himself to the opinion that, in England, it is better for a man's worldly prospects to be a drunkard,

than to be smitten with the divine dipsomania of the original investigator. I am inclined to think he was not far wrong. And, be it observed, that the question is not, whether such a man shall be able to make as much out of his abilities as his brother, of like ability, who goes into Law, or Engineering, or Commerce; it is not a question of 'maintaining a due number of saddle horses,' as George Eliot somewhere puts it—it is a question of living or starving.

"If a student of my own subject shows power and originality, I dare not advise him to adopt a scientific career; for, supposing he is able to maintain himself until he has attained distinction, I cannot give him the assurance that any amount of proficiency in the Biological Sciences will be convertible into, even the most modest, bread and cheese. And I believe that the case is as bad, or perhaps worse, with other branches of Science. In this respect Britain, whose immense wealth and prosperity hang upon the thread of Applied Science, is far behind France, and infinitely behind Germany.

"And the worst of it is, that it is very difficult to see one's way to any immediate remedy for this state of affairs which shall be free from a tendency to become worse than the disease.

"Great schemes for the Endowment of Research have been proposed. It has been suggested, that Laboratories for all branches of Physical Science, provided with every apparatus needed by the investigator, shall be established by the State; and shall be accessible, under due conditions and regulations, to all properly qualified persons. I see no objection to the principle of such a proposal. If it be legitimate to spend great sums of money on public Libraries and public Collections of Painting and Sculpture, in aid of the man of letters, or the Artist, or for the mere sake of affording pleasure to the general public, I apprehend that it cannot be illegitimate to do as much for the promotion of scientific investigation. To take the lowest ground, as a mere investment of money, the latter is likely to be much more immediately profitable. To my mind, the difficulty in the way of such schemes is not theoretical, but practical. Given the laboratories, how are the investigators to be maintained? What career is open to those who have been thus encouraged to leave bread-winning pursuits? If they are to be provided for by endowment, we come back to the College Fellowship system, the results of which, for Literature, have not been so brilliant that one would wish to see it extended to Science; unless some much better securities than at present exist can be taken that it will foster real work. You know that among the Bees, it depends on the kind of cell in which the egg is deposited, and the quantity and quality of food which is supplied to the grub, whether it shall turn out a busy little worker or a big idle queen. And, in the human hive, the cells of the endowed larvæ are always tending to enlarge, and their food to improve, until we get queens, beautiful to behold, but which gather no honey and build no comb.

"I do not say that these difficulties may not be overcome, but their gravity is not to be lightly estimated."

It is pointed out that the creation of Faculties of Science will, to a certain extent, remedy the present lamentable condition of things to which we have so often called attention.

"It is possible to place the scientific inquirer in a position in which he shall have ample leisure and opportunity for original work, and yet shall give a fair and tangible equivalent for those privileges. The establishment of a Faculty of Science in every University implies that of a corresponding number of Professorial chairs, the incumbents of which need not be so burdened with teaching as to deprive them of ample leisure for original work. I do not think that it is any impediment to an original investigator to have to devote a moderate portion of his time to lecturing, or superintending practical instruction. On the contrary, I think it may be, and often is, a benefit to be obliged to take a comprehensive survey of your subject; or to bring your results to a point, and give them, as it were, a tangible objective existence. The besetting sins of the investigator are two: the one is the desire to put aside a subject, the general bearings of which he has mastered himself, and pass on to something which has the attraction of novelty; and the other, the desire for too much perfection, which leads him to

"'Add and alter many times
Till all be ripe and rotten;'

to spend the energies which should be reserved for action, in whitening the decks and polishing the guns.

"The necessity for producing results for the instruction of others, seems to me to be a more effectual check on these tendencies than even the love of usefulness or the ambition of fame."

It would indeed be a happy solution of the difficulty if it could be solved in this way, but we confess that on this point we fear that the system advocated by Mr. Huxley will not be all that is needed.

In the first place, take the present appointments to Chairs; are they, as a rule, given to the most distinguished investigators? If not, why not, and why should the present system be altered? In our opinion the present system of appointing teachers is good so long as large ranges of knowledge have to be professed. Take many of our present professors; are they as encumbered by teaching as the German professors are for instance? and yet where are their researches? do they not figure much more often in the "List of Examiners" than in the "Philosophical Transactions"? If these things are so, no benefit will accrue from a mere increase of numbers unless the present pay be largely increased.

There is also another most important point, and here again we quote from the Address:—

"It is commonly supposed that anyone who knows a subject is competent to teach it; and no one seems to doubt that anyone who knows a subject is competent to examine in it. I believe both these opinions to be serious mistakes: the latter, perhaps, the more serious of the two. In the first place, I do not believe that anyone who is not, or has not been, a teacher is really qualified to examine advanced students. And in the second place, examination is an art, and a difficult one, which has to be learned like all other arts."

Are then investigators to be made teachers and examiners in order that they may live, regardless of the fact that they cannot teach, and though they may be ignorant of the "art" of examining?

We believe that powers of teaching and powers of investigation by no means go together, though they are united in some great men like Mr. Huxley; and we believe, further, that on this ground alone the idea of making a man teach in order that he may carry on researches is bad in principle: it is even worse than this, because it is apt to cause the public to underrate research—to think that the end of all research is to teach, while in point of fact the end and aim of the acquisition and teaching of all old knowledge is the acquirement of new knowledge.

It is a source of satisfaction to us that Prof. Huxley agrees with us on the main point, for we are certain that when once the principle is conceded, practical methods of carrying it out, among which undoubtedly that in-

sisted on by the Lord Rector will find place, can easily be found; methods against which no objection can be urged, and from the application of which a tremendous increase in the rate of advancement of knowledge in this country may be anticipated.

POST-TERTIARY GEOLOGY *

The Great Ice-Age and its relation to the Antiquity of Man. By James Geikie. (W. Isbister and Co. 1874.)

II.

WE must next turn to beds which furnish conclusive proof of a return of cold conditions, the well-known shell-bearing clays found here and there along the coast of Scotland. The fossils and the physical condition of these beds both concur in telling the same tale, that an Arctic climate again prevailed in Britain. These deposits are marine, and have not been met with at a greater height above the sea than 360 feet, and they were therefore formed towards the termination of the period during which the land was emerging from the sea. Evidence of a similar change of climate is, however, found in the interior of the country. In the Highland glens and the high valleys of the Southern Uplands morainic deposits, distinguishable from those of the earlier ice period, are of common occurrence, sometimes scattered loosely over the mountain slopes, sometimes arranged in ridges or lines of mounds across the valleys after the fashion of terminal moraines. The climate, therefore, must have become again severe enough to allow of the accumulation of ice; but, since the second set of glaciers is shown by the moraines which they have left behind them to have been confined to the high ground, and each restricted to its own valley, the cold must have been far less intense than during the period of the first glaciation.

The second period of cold, however, passed away, and the record of its gradual disappearance is written for us in this way. In many of the upland valleys concentric lines of mounds, each marking the terminal moraine of a glacier, are arranged one within the other, and as we ascend these piles are found to grow more and more puny, till they at last vanish altogether. From this we see, as clearly as if the operation had gone on before our eyes, how each glacier shrank back step by step into the heart of the mountain glens, and at last yielded to the gradual amelioration of the climate, and melted entirely away. Another train of reasoning leads us to the same conclusion. The rising of the land was not continuous, but broken every now and then by pauses, and during each of these the sea cut a notch or shelf in the rocks and occasionally spread out terraces of shingle and silt, forming what are known as Raised Beaches. These beaches occur at many different levels, from 1,500 feet down to a few yards above the mean-tide level. The higher of these beaches furnish evidence of somewhat Arctic conditions, but as we descend in the series these traces become less pronounced.

We are now approaching the close of the glacial epoch, and the climate, though still colder than now, was approximating to what it is at present.

The author goes on to show, from a consideration of submerged forests, how the elevation of the land went on till Britain was raised above its present level, and probably connected by a land surface with the mainland of Europe; and points out how the continental climate thus produced will account for the dense forests which formerly clothed our island, while a return to insular conditions resulted in a decay of the woods and the growth of peat mosses.

Lastly, our country became again dissevered from the continent, and the submergence which brought about this change went on till the land was sunk somewhat below its present level; while it rose into its present position, low level raised beaches were formed, among which the well-known 25-feet-beach is most conspicuous.

Such then is the succession of physical changes which the Drift-deposits show has taken place in our island.

The author has passed in review also the contemporaneous formations of Scandinavia, Switzerland, and North America, and pointed out how the story they tell agrees in its main features with that deduced from our own glacial formations.

Had he done no more than this he would have produced a work of surpassing interest and value, but the concluding chapters of his book will perhaps attract more attention than any other part of it, for they deal with a question that comes in a measure personally home to us, the antiquity of man and the date of his first appearance in Britain.

The oldest races of men of which traces have yet been discovered are known as the Stone-folk, because they fashioned their implements out of stone and seem to have been unacquainted with the use of metals. These Stone-folk are clearly distinguishable into two classes—the older, known as Palæolithic, merely chipped stones into shape; the later, or Neolithic, had advanced a step farther, and constructed tools highly polished and otherwise more finished than those of their predecessors. We also find associated with the traces of Palæolithic man a group of mammals now wholly or locally extinct, while the mammals accompanying the remains of Neolithic man are many of them still indigenous to the country. In connection with this subject the author has brought prominently into notice a fact which had not received the attention it deserves, that nowhere have any signs been detected of gradual improvement on the part of Palæolithic man, by which he may have passed from abject barbarism to the more advanced skill of his Neolithic successor, but that, on the contrary, the two races are everywhere sharply marked off from one another. In the same way the accompanying groups of mammals are essentially distinct, and we nowhere find traces of the dying out of the one and the gradual coming in of the other. But one inference can be drawn from these facts: between the time when the Palæolithic race inhabited Britain and the coming in of the Neolithic race a long interval must have elapsed, during which man was by some means or other driven out of the country, and went through elsewhere the long series of modifications by which he was himself advanced in civilisation, while at the same time the group of animals associated with him became totally changed. Now we know of no physical change since the second glaciation of the country which could have been the cause of such a migration, for all the evidence both here and elsewhere tends to show, that whatever change of climate has occurred between that event and the present day has been

* Continued fro p. 321.

steadily in the same direction—that of improvement. But the great submergence, and severe period which followed it, would exactly bring about the required result, if it can be only shown that the age of Palæolithic man preceded these occurrences.

There is no antecedent improbability in such a supposition; the mild periods that recurred during the formation of the Till may well have been warm enough to allow of northern mammals, and subsequently, as the climate improved, of Palæolithic man and southern forms migrating into our area, to be again driven out each time a return of cold brought the ice-sheet down over the lowlands, and finally expelled, never again to return, by the great submergence. But more than this, our author has shown how anomalies, hitherto inexplicable, receive an easy solution on this hypothesis; how, for instance, it accounts for the mingling of northern and southern forms of mammals in the palæolithic beds; and how it gives a reason for the fact that palæolithic river-gravels are confined to those parts of Britain which were not covered by the ice-sheet, while the palæolithic deposits found in caves are not so restricted.

The hypothesis therefore stands on a firm basis, and the conclusion is irresistible that Palæolithic man was of interglacial—may be of preglacial—date. Thus much had been dimly felt rather than demonstrated by previous thinkers; but Mr. J. Geikie has shed a flood of light on the subject by pointing out that man was driven out of our country by the great submergence; that Britain was not again peopled till the elevation that followed connected it with the continent; and that the colonists belonged to the Neolithic race. In this way he has satisfactorily accounted for the great gap that exists between the two divisions of the Stone-folk.

The reasonable limits of an article are well-nigh reached, but we have by no means exhausted the contents of this comprehensive volume. The chapter on lakes must not be passed by altogether, for besides being a lucid exposition of Prof. Ramsay's theory of the formation of rock-basins, it is illustrated by an admirable map and section of Loch Lomond, and by a beautiful chart of part of the western coast of Scotland, which shows that these hollows are not confined to the land, but are also dotted over the shallow bed of the adjoining sea in exactly the places where a glacialist would expect to find them. The chapter on the English Drift would itself furnish materials for a review, as would also the note distinguishing the formations which are considered to have yielded traces of ice action. On the latter head we may point out that the presence of glaciers or icebergs is not in itself proof of a glacial epoch. Where we find, as in the Permian beds, evidence of the presence of ice at localities so far apart as Ireland, the west of England, and the centre of Germany, it looks like an indication of wide-spread severity of climate; but such a case as the Brecciated Beds of the Ord is better explained by a local development of glaciers, specially as the fauna of the associated strata forbids the existence of a general low temperature. It is worthy of note that these periods, which give the most satisfactory indications of glacial conditions, come close upon others, when a genial climate prevailed far up into northern latitudes; the Permian, for instance, followed hard upon the Carboniferous, and the Miocene epoch, if the glacial character of portions of it be fairly established, would yield a still more striking instance. But these juxtapositions of strongly-contrasted phases of climate, so far from being matter for surprise, are a necessary result of Mr. Croll's theory, according to which each hemisphere would, during a period of high eccentricity, experience alternately the severity of a glacial epoch and eras of almost perpetual spring.

Space will allow us to point out one only of the numerous results which will probably follow from the conclusions of this work. They must lead to a revision of our nomenclature of the Tertiary strata. The conditions of the Pliocene epoch were merely the commencement of a series of changes which received their full development during the Glacial era; and the latter is linked on by an equally unbroken succession of events with modern days. If therefore we are to have a Post-tertiary, Quaternary, or Recent Period, it should on physical grounds include Pliocene times; while the continental character of the Miocene epoch in Europe, and the important events that brought it to an end, mark it out as the natural termination of the Tertiary era.

In conclusion we have only to express a hope that the imperfect sketch we have given of the Great Ice Age may lead many readers to arrive at a fuller appreciation of its merits by turning to the work itself.

A. H. GREEN

SCHWEINFURTH'S "HEART OF AFRICA"

The Heart of Africa; or, Three Years' Travels and Adventures in the Unexplored Regions of the Centre of Africa. By Dr. Georg Schweinfurth. Translated by Ellen E. Frewer. 2 vols. (London: Sampson Low and Co., 1874.)

THE "Heart of Africa" is a valuable contribution to African literature, and we lay down the last volume with regret. This regret is enhanced by the grievous disappointment all geographers must feel that a man so capable and so reliable as Dr. Schweinfurth should have limited his scientific acquirements to botany and natural history without having qualified himself as a traveller by the use of astronomical instruments.

When we first glance at the elaborate map of the author's travels, embracing an extraordinary series of curves, zigzags, and the like, until we reach his most southern limit, we are delighted with this apparently valuable addition to geography, and we feel a first impulse to congratulate Germany as an ally in Central African Exploration, but to our complete dismay after these ardent expectations we find ourselves actually without one astronomical observation.

As geographers, we really have a right to complain. If Dr. Schweinfurth had been an uneducated adventurer, or even a mere sportsman attracted to wild countries by a love of wandering, we should have regretted a barren geographical result after an arduous journey of three years. Dr. Schweinfurth is, on the contrary, a man of scientific education and a botanist—in addition to being an accomplished draughtsman. He is a man of cultivated tastes, and he evidently combines the qualities requisite for a traveller in wild countries. Why should he not have fitted himself prior to his voyage by a few

months' study for the only practical and reliable work of a geographer or scientific traveller? In the absence of astronomical observations we can only regard his map as the author's *idea* of his journey. We have no compass bearings or any reference to such observations having been taken. We must therefore accept his map as simply a conscientious endeavour to introduce us to his wanderings; at the same time, geographically speaking, we can only allow that he has been wandering about in the "Heart of Africa." It is with regret, therefore, that we cannot accept him in the first rank of geographers. A future traveller over the same ground may contest every position; thus, instead of our author's journey having added to our geographical knowledge, it may simply add to those geographical strifes which are the inevitable results of un-scientific journeys.

Having, as a matter of duty, expressed this opinion upon a work otherwise most valuable, it is a pleasure to be able to grasp one geographical fact that is well established, and is independent of astronomical observations. This is the watershed towards the West which forms the boundary of the Nile Basin. The large flow of water discovered by Dr. Schweinfurth is passing towards the Atlantic. This at once disproves the theories laid down by Livingstone, but never accepted by geographers, that he rivers to the west of the Tanganika Lake flowed northward to the Nile. As Schweinfurth passed out of the Nile Basin in about 28° E. long., so also Livingstone arrived in a western watershed south of the equator in about the same meridian.

The botanical information collected by Dr. Schweinfurth is invaluable, and can only be estimated by a professional botanist. We envy the traveller in many of his floral rambles, which are described with the energy and vividness of an enthusiast. Nothing new has been added to the known list of African fauna. We conclude, from the description of the habits of the so-called "rock rabbit," that our author means the "hyrax," which, although resembling a rabbit in appearance, is not a rodent.

Dr. Schweinfurth having been properly supported by an introduction from the Berlin Academy was saved many difficulties to which other travellers have been subjected; he was well received by Djiaffer Pacha, the Governor-General of Soudan, at Khartoum, who handed him over to the care of one Ghattas, a Coptic slave trader and ivory merchant. Ghattas entrusted him to the guidance of his own people, who appear to have behaved extremely well. Dr. Schweinfurth had every opportunity of examining the mysteries of the slave trade, and he is perfectly right in his description of the immense importance of the Darfur and Kordofan route, by which vast multitudes are conveyed who can thus elude the cruisers on the White Nile. At the same time the author is in error and has been purposely deceived by his informants (themselves slave traders) when (p. 429, vol. ii.), speaking of the upper district of the White Nile, inclusive of the Albert and Victoria Lakes, as one of the territories that form the sources of the slave trade in north-eastern Africa, he says, "The expedition of Sir Samuel Baker has stopped this source. The annual produce in the most favourable years did not exceed 1,000." There were no less than ten slave stations situated in the territory under Sir Samuel Baker's command. In each of these stations were at least 1,000 slaves.

The last act of Sir Samuel Baker, on his homeward route, was to overtake three vessels from the Bohr, lat. 5°·20 N., with 700 slaves on board, which were openly on their route to pass the Government station of Fashoda! thus proving what Dr. Schweinfurth himself states respecting the connivance of the Egyptian officials, p. 442, vol. ii.—"In Kordofan, where there is a resident Egyptian Governor, the trade is truly enormous, and there is now as well the slave-trade from Darfur." In a cursory review of the slave-trade Dr. Schweinfurth makes a remark that few Englishmen would sanction, p. 433, vol. ii.—"Two great nations have speeded on the work, England in theory, North America in practice." If the payment of twenty millions sterling for emancipation was not the most practical, and not only theoretical, work, we really do not understand what practice means.

It would have been interesting had Dr. Schweinfurth given us more details of the ivory trade carried on by the people who acted as his chaperons in Africa. These were avowedly slave traders, and we should be gratified to learn that they formed some exception to the rule, and actually traded with merchandise instead of bartering slaves and stolen cattle for ivory.

The reward of ignorant ages to the returned traveller was general incredulity. Even in the present day there are ignorant persons who question the existence of cannibalism. Dr. Schweinfurth has arrived fresh from the cannibals of Monbuttoo with human skulls and bones almost warm from the saucepans of the savages. He can even describe the sauces which these gourmands use in their dainty dishes. Mushrooms and capsicums for a "sauce piquante aux champignons" are the literal civilised adjuncts for a dish off a stewed baby, only two days old, whose mother had deserted it! The baby was dying while the preparations for cooking it were already commenced. This is the real truth and no traveller's joke, as the babies and fond mothers would quickly discover should they visit the tribe of Monbuttoo. It may be asked, "How did Dr. Schweinfurth escape?" but it must be remembered that the Monbuttoo do not eat men of science, who are generally very lean. A fat missionary, with a family fresh from Exeter Hall, may meet with immediate attention, with the warm but brief Monbuttoo invitation, "walk in."

It would be useless for us to closely criticise this book. Few books are perfect. There may be a little excess of detail of the dull routine of African daily life that if omitted would have reduced two bulky volumes to a more convenient size. But on the other hand, some people like bulky volumes and enjoy as many pounds avoirdupois as they can obtain for their money; just as some people, especially the rural population, enjoy long sermons.

We cordially recommend all interested in exploration to read the book, at the same time reminding them that they may safely rely upon the high character and status of the author; for although Dr. Schweinfurth fails as a scientific geographer, he in no way fails as a scientific explorer devoted to the particular object of his studies—botany. In this branch of science he is better qualified than any former African traveller.

Such men as Dr. Schweinfurth will always have the

regard and esteem of all true friends of Science; he belongs to the same metal that has already formed a wedge which will force open the secrets of inner Africa.

OUR BOOK SHELF

Adulterations of Food, with short Processes for their Detection. By Rowland J. Atcherly, Ph.D., F.C.S. (London: W. Isbister & Co., 56, Ludgate Hill, 1874.)

THE attempt to notice the adulterations of food in 100 pages of large type is a somewhat rash one, and it is not therefore surprising that the author of the treatise is frequently compelled to dismiss his subject in a very cursory manner.

For two of the classes of readers whom he addresses, the dealer and consumer, the work will no doubt be of use, and it is also likely to be useful to the chemist, as affording him a brief conspectus of the most likely adulterants in any particular article. Of what use, however, the last 12 pages of letterpress describing the making and use of volumetric solution are to the "trained chemist," to whom the author addresses them, we are at a loss to conceive.

The information given in the part upon adulterations is generally sound, though the statement on p. 34 that prussic acid is found when nitro-benzol has been used as a flavouring is absurd; so far is this from being the case, that it would be an indication of the use of a genuine but insufficiently purified oil of bitter almonds. The process for detecting alum in bread on p. 15 is also very unsatisfactory, and certainly not adapted for the use of either dealer or consumer. The book concludes with 21 neatly executed cuts of various starches, chicory, cocoa, tea-leaves and adulterating leaves found in tea, &c., as seen under the microscope. In conclusion, we would advise the author in a future edition to considerably expand the part on adulteration and to entirely omit the part intended for the "trained chemist," leaving that person to obtain his information on volumetric solutions from the proper sources. R. J. F.

An Easy Introduction to Chemistry. Edited by the Rev. Arthur Rigg, M.A., late Principal of the College, Chester. (Rivingtons: London, Oxford, and Cambridge, 1873.)

THE present work, founded, as the editor states, on a "First Book of Chemistry," by Dr. Worthington Hooker, published in America, is intended for the use of children. Mr. Rigg calls attention to the inquiries of "young persons" as generally suggested by their observations of things touched and handled, and states that his aim has been "To supply information in a form which it is hoped may be intelligible and interesting to all parties concerned in thus learning to read the ever open book of nature."

The intention is a worthy one, and we have no doubt that the work will serve its purpose in instructing some of its readers, though we doubt if it will prove very intelligible for "persons" so young as those to whom the style of its commencement would seem to prescribe its use. We do not say this with any desire to find fault, for it would indeed be difficult to place the information in a simpler form than has been done, but because of the great difficulty of convincing young minds of the alterability of matter. Either talking or reading alone is quite incompetent to do this. Without experimental illustration they are utterly meaningless except to well-advanced intellects, and even there cannot do much, as anyone can tell who has had the honour of meeting the chemist whose knowledge extends not beyond books. In fact, chemistry is not to be taught without the laboratory and its experiments, and Mr. Rigg has shown his sense of their importance by the insertion of 46 beautifully-executed woodcuts of experiments and a frontispiece of a laboratory with its apparatus and fittings.

Excepting in a school, however, the "young persons" of the preface are not likely to meet with the actual experiments of which illustrations are supplied, and those that are of sufficient age to go to such a school might surely have a rather more advanced book placed in their hands. The question, however, which a reviewer ought to ask himself is, Is the book such a one as would fairly carry out the author's intention? and to this we must, in this case, answer "Yes." Granting the possibility of teaching chemistry to young children, Mr. Rigg's book would certainly serve its purpose well. With regard to his facts, Mr. Rigg is, as a rule, sound; but we must demur to his statement on p. 134, that "If (silica) is to these (grasses and grain) and other plants very much what bones are to animals;" and again, on p. 167, "Every stalk of grain or grass is chiefly wood. In both cases fine particles of flint are scattered in the wood to make it firm enough to stand even in a gale of wind." The experiments of Sachs and others have long since disproved this theory. Such blemishes as these are, however, of but little moment when the main principles of the science are the object of teaching, and on these Mr. Rigg is perfectly orthodox. We must, in conclusion, compliment the publishers on the very elegant get-up of the book.

Die Rohstoffe des Pflanzenreiches: Versuch einer technischen Rohstofflehre des Pflanzenreiches. Von Dr. Julius Wiesner. (Leipzig: Engelmann, 1873. London: Williams and Norgate.)

THIS is one of those elaborate German works which seem as if they were intended completely to exhaust the subject of which they treat. Every substance of economical or technical importance which is obtained from the vegetable kingdom is treated of in detail from the point of view of its practical utility rather than its physiological history; its chemical, mechanical, and microscopical properties, the mode of its preparation or manufacture, and its utility in the arts or commerce, are described. The book is, in fact, a repertorium of technical botany.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

On a Proposed Statistical Scale

AT a lecture last Friday evening, at the Royal Institution, I spoke on a subject which happens to lie at the meeting-point of many special sciences, and therefore, as I am desirous of having it well discussed, and from many points of view, it seems to me best to state it afresh in your columns for that purpose. It refers to the *definition* of the estimated *degree of development* of any quality whatever, without reference to external standards of measurement. The scale I propose depends on two processes; the one is securely based on the law of statistical constancy, the other is doubtfully based on the law of frequency of error. (1) At present we are accustomed to deal with averages and the like, which can only be obtained by measuring *every* individual by a *detached standard scale*, and going through an arithmetical process afterwards. Now I want to deal with cases for which no external standard exists, and I propose to proceed in quite another way, on the principle that *intercomparison* suffices to define. We have only to range our group in a long series, beginning with the biggest and ending with the smallest; and then we know by the law of statistical constancy that the individual who occupies the half-way point, or any other fractional position of the entire length, will be of the same size as the individual who occupies a similar position in any other statistical group of similar objects. We state his size with statistical precision by saying that his place is so and so in a series. We appeal to a standard which lies dormant in every group, and which a statistician can evoke, for temporary purposes of comparison, whenever he will. (2) What places in the

series shall we select for our graduations? Equal fractions of its length will never do—I mean such as one-tenth, two-tenths, &c. —because of the great inequality of the variation in different parts of the series, being insensible between those whose position is near its middle and great between those at either end. I propose to use a scale founded on the law of Frequency of Error, which gives a scale of equal parts wherever that law applies, and I use the "probable error" for the unit of the scale. Thus, in a row of a hundred individuals the graduations of $+2^\circ$, $+1^\circ$, 0°, -1°, -2°, respectively would be at the following places, in percentages of the length of the series:—2, 9, 25, 50, 75, 91, 98. We know that the law of Frequency of Error applies very closely to the linear measurements of the human form. Now suppose that I want to get the average height and "probable error" of a crowd of savages. Measuring them individually is out of the question; but it is not difficult to range them—roughly for the most part, but more carefully near the middle and one of the quarter points of the series. Then I pick out two men, and two only—the one as near the middle as may be, and the other near the quarter point, and I measure them at leisure. The height of the first man is the average of the whole series, and the difference between him and the other man gives the probable error. The question I put is, whether any more convenient subdivision of a series can be suggested for *universal use* than that above mentioned. Its merits are, that it applies very fitly to linear measurements of all natural groups; also to errors of observation, which are akin to many of the moral qualities, for the measurement of which the scale is especially needed. It would not apply to weight, but is less out of relation to it than most persons might think, because weights do *not* vary as the cubes of the heights. Tall men are often thin, and short ones are fat, and the curious fact seems thoroughly verified that the general relation between height and weight is *strictly* as the *squares*. (See Gould's "Sanitary Memoirs of the War of the Rebellion," Cambridge, U.S., 1869, p. 408–410.) If we arrange a series and graduate it according to equal differences of the squares of the heights of the men, we are not so far astray as if we had dealt with the cubes. But I cannot imagine any quality, unless possibly music and memory, to vary so rapidly towards the large end of the series as the latter division would show. To sum up: subdivision in *equal* parts is of no use practically, and is therefore out of the question; the law of error will do very accurately for many large groups of cases; the law of error modified by being brought into relation to bulk will rarely, if ever, be right for other qualities. It therefore seems to me reasonable to adopt the law of error series, as the best compromise, and to accept it as "the common statistical scale." If, for example, I estimate a soldier's energy at $+2^\circ$ (S.S.), I state what everybody who cared to inquire into the subject would construe in exactly the same sense as I used the phrase, and he would also be inclined to believe, until better informed, that the difference between such a man's energy and that of a man of $+0^\circ$ (S.S.) was twice as great as between him and a man of $+1^\circ$ (S.S.).

Lastly, how can we best find individuals who represent the 0°, $\pm 1^\circ$, &c., of any and every quality, that they may be studied and their abilities illustrated and described, so as to serve as permanent standards of reference? These would gradually give us means of finding the equivalent of the S.S. graduation in the natural scale—as we might learn to say, $+4^\circ$ (S.S.) of energy $= +3^\circ\cdot5$ in the natural scale. Those who have to deal with bodies of men, whether as examiners, instructors, masters, overseers, or officers, could best tell. How about the ordinary subjects of competitive examination? Is there any optical observation made under (sensibly) identical circumstances and with (sensibly) identical instruments, of which the probable error of each observer is known? If one could only get two or three hundred nautical observers together, and make them take sextant angles of the same objects, and learn the probable errors of each, we should have data to give us once for all the values of the S.S. as regards ability to observe, in terms of absolute values. Can no drawing-master give accurate descriptions of the delicacy of touch of his pupils, corresponding to the graduations of the S.S. scale? How about mechanical manipulation among operatives? How about music and memory? Each separate quality requires and deserves a monograph, which, once thoroughly well done, would become a most valuable standard of comparison and check upon the S.S. scale, which it must be remembered is securely based on no ground except that of statistical constancy, but which, when it *proves* to be a scale of equal parts, is doubly acceptable.

I will not go on writing now, being rather desirous of raising discussion and learning more, than of saying all my say.

42, Rutland Gate, S.W. FRANCIS GALTON

Simultaneous Meteorological Observations

WITH reference to the scheme of international simultaneous observations proposed by the War Department of the United States and adopted by the Meteorological Congress at Vienna in September last, a provisional arrangement was entered into at Vienna, between General Myer and myself, at his desire, by which the Scottish Meteorological Society was to assist the American Government in carrying out the proposed scheme by an exchange of meteorological observations between the two bodies. At a meeting of the Council of this Society on February 9, a letter was read from General Myer, dated January 27, 1874, formally requesting the co-operation of this Society in carrying out the international scheme, which letter being identical with the one on the same subject published in NATURE (vol. ix. p. 300), it is unnecessary to subjoin.

A considerable number of observers have been already obtained in connection with the scheme, and copies of the American *Monthly Weather Review* and *Daily Meteorological Record* have, along with the special schedules for the observations, been sent to them, as an acknowledgment on the part of the American Government for their assistance in the work. The Council are ready to receive the assistance of others of their own observers, and of any other observers who may be willing to cooperate in this cosmopolitan scheme, from which cosmopolitan benefits may be confidently looked for.

ALEXANDER BUCHAN

Scottish Meteorological Society, Edinburgh, March 2

The Limits of the Gulf-stream

MUCH discussion has recently taken place respecting the limits of the Gulf-stream, and the Admiralty Chart of the North Atlantic, published last year, is supposed to embody all that is known of its boundaries. My observations, however, which have extended over a series of years, differ so widely from it that I am induced to send you an abstract chart of them.

In December 1872 I found the stream wedged in to a distance of fifteen miles off Cape Hatteras, and following the coast-line at that distance to Roanoke Sound. On arriving in Norfolk I found that the reports of several ships corroborated my observations.

The remarkable bend east of George's Shoals is confirmed by H.M.S. *Gannet*, and also by the Nantucket fishermen and pilots.

Maury, in his "Physical Geography of the Sea," makes the stream, in summer, wash the southern shores of Newfoundland, but in no month of the year have I found it so far north as the red line in the accompanying chart. I am of opinion that if it once passed over the bank every codfish would be destroyed. The highest temperature recorded by me in September on this line is 56°.

At the points of sudden change I have seen the ripples at the distance of a mile previous to entering them. Those which are recorded may be relied on to a mile, as I have discarded those made from dead reckoning. In every case the deep blue colour of the sea, the presence of sun-fish, Portuguese men-of-war, and numerous *débris*, confirmed the observations made with the thermometer, and I may add, what is of more importance to seamen, the strong easterly set.

The southern boundary of the stream is taken from the observations of five years. As summer advances it becomes more difficult, when east of Bermuda, to detect the line of demarcation, for the rays of the sun heat the water almost to Gulf-stream temperature right down to the limit of the trade-wind. From the data which I have been able to collect, as well as from personal observation, the limits of icebergs in the Admiralty Chart appear to be equally erroneous. To me it appears impossible that bergs could drift square across the heated waters of the Gulf-stream to lat. 39° N. almost in the teeth of the prevailing summer winds, and a strong north-easterly set of two miles per hour. The Admiralty Chart gives the current a higher velocity.

The most southern iceberg ever seen by a Cunard steamer (and there cannot be a higher authority) was in lat. 43° 10′ N., long. 49° 40′ W., and the most eastern, which has come under my observation, by the *Grace Gibson*, on June 11, 1868, which ship passed four between lat. 43° 15′ N. and 43° 20′ N. and long. 41° 20′

W. to 42° 10′ W. It certainly must appear singular to geographers that the limits of the best-known stream in the world should be so ill-defined; but the temperature of the sea at the places marked in the chart cannot suddenly change 12° from any other cause than the irruption of the Gulf-stream or the ordinary waters of the ocean. Had it occurred in a single season only, the correctness of the observations might have been impugned; but extending, as they do, over several years, their accuracy cannot be challenged.

It is the opinion of many that the Gulf-stream is extending its boundaries northward, and ameliorating the climate of the British islands. Such an assumption is not an impossibility, although there are no changes of volume or velocity at its outlet into the Atlantic. There are, however, grounds for believing that the Labrador current does not run with its former force, as icebergs are seldom seen south of the parallel of 43° 30′ north latitude. Observation can alone confirm this theory, but whether correct or not it in nowise affects the accuracy of my data.

WM. W. KIDDLE

U.S. White Star Mail Steamship *Oceanic*, Feb. 2

[We have received a chart from Mr. Kiddle; but it is too large for insertion in NATURE.]

A Lecture Experiment

MR. TAIT's letter in NATURE of February 26 calls to mind an effective lecture illustration I have used in my classes to illustrate a fog or cloud produced by cooling air containing moisture. Instead of using an air-pump as described in "Heat, a mode of Motion," take a flask of one or two litres capacity, rinse it out with distilled water, and attach to the neck a cork and glass tube of about twenty or thirty centimetres in length. Place the glass tube in the mouth and exhaust, when a dense cloud will be formed; then on blowing into the flask the cloud disappears. The cloud may be produced and dissolved as often as wished, and if a beam from the oxy-hydrogen light be sent through the flask, the experiment becomes very effective.

Midland Institute, Birmingham C. J. WOODWARD

The "Treasury of Botany"

IT might be inferred from your notice of the new edition of the "Treasury of Botany" (NATURE, vol. ix. p. 300) that the stereotyped pages of the original text of that work—of which you are pleased to speak in terms of commendation—had been reprinted without alteration. Will you allow me space to state that this is by no means the case (as indeed is stated in the preface), but that a large number of corrections have been made, as may be detected by a keen eye in consequence of the slight difference which is observable in the type where the alteration has extended over two or three lines or more. Hence it is not to the Supplement alone that the reader must look for such of the "additions to botanical knowledge made during the last eight years" as it has been found practicable to include in the revised edition.

THOS. MOORE

[WE are glad of the opportunity afforded by the foregoing letter of repeating our opinion, already expressed, that in the department of botanical nomenclature and classification, the new edition of the "Treasury of Botany" is an altogether admirable and indispensable work. It is in this department only, or almost exclusively, that the corrections alluded to by Mr. Moore—and to which we perhaps ought to have called special attention—have been made, at least as far as we have been able to detect. We regret that we cannot withdraw from our statement that the same care has not been taken with the histological and physiological section. We might quote a number of instances in support of this assertion—a very ungracious task in speaking of a work so excellent in other respects—but will only refer to a single one. Notwithstanding that a very good and useful epitome of the more important properties of "Cellulose" is given in the Supplement, the statement is allowed to stand in the article in the body of the work, that "its composition, according to the latest analysis, is $C_{24}H_{20}O_{10}$" a formula which does not, and never did, even under the old notation, represent anything near its composition. —A. W. B.]

The Moons of Uranus

IN your "Notes," this week, it is stated that since Mr. Lassell's observations at Malta, no one has seen the four moons of Uranus, until the re-discovery of the two small ones lately with the new Washington telescope.

In 1869-70, the planet was observed with the Melbourne reflector; the observations were specially directed to the disc, but at the same time the positions of the four satellites were noted on successive nights and thus identified.

I speak from memory, but have no doubt that the observations are to be found in the Melbourne records. The statement "have actually been measured by Prof. Newcomb," probably refers to position, angle, and distance.

March 1 L. S.

MEN OF SCIENCE, THEIR NATURE AND THEIR NURTURE*

THE lecturer spoke of the qualities by which the English men of science of the present day were characterised; he showed the possibility of defining and measuring the amount of any of those qualities, and concluded by summarising the opinions of the scientific men on the merits and demerits of their own education, and gave his interpretation of what, according to their own showing, they would have preferred. His data were obtained from a large collection of autobiographical notes, most obligingly communicated to him, in response to his requests, from the larger part of the leading members of the scientific world. He had addressed 180, who, being Fellows of the Royal Society, had, in addition, gained medals or filled posts of recognised scientific position; 115 answers had already been received, of which 80 or 90 were full and minute replies to his long and varied series of questions. He dealt with only a small part of his deductions from this valuable material, referring to a forthcoming work for the rest.

Regarding the chief qualities in the order of their prevalence among the scientific men, they were—(1) Energy both of body and mind; (2) Good health; (3) Great independence of character; (4) Tenacity of purpose; (5) Practical business habits; and (6) What was usually the salt of the whole, strong innate tastes for science generally or some branch of it. He illustrated his remarks by reading many anonymous extracts from the returns, and explained in what way a notable deficiency in any of the above-mentioned qualities would tend to disqualify a man from succeeding in science.

As to the measurement of qualities, it was argued that the law of constancy in vital statistics might be taken for granted, being evidenced by the experience of insurance offices against fire, death, shipwreck, and other contingencies, always with the proviso that the facts are gathered with discretion, on well-known general principles. Hence we may say with assurance, that although two common nuts may differ, yet the contents of different packets, each containing 1,000 nuts, will be scarcely distinguishable, for the same number of nuts of different sizes will be found in each. Let the contents of the several packets be each arranged in a long row, in order of size, beginning with the biggest nut and ending with the smallest, and place the rows rank behind rank; then by the law of statistical constancy the nuts in the same *files* will in all cases be closely alike (except the outside ones, where more irregularity prevails). Again, if we incorporate two rows into one of double length, still preserving the arrangement as to regular gradation in size, the centre nuts of the two original series will still be found at or near the centre of the compound series, the nuts in quarter positions will still be in quarter positions, and so on. Hence, whatever be the length of the series the *relative* position in it of the nut will be a *strict criterion* of its size. This is of course equally true of all groups of qualities or characters

* Lecture on Friday evening, Feb. 27, at the Royal Institution, by Franci Galton, F.R.S.

whatever, in which the law of statistical constancy prevails, the series, in each case, being arranged according to gradations of the quality in question. Each individual is measured against his neighbour, and it is quite unnecessary to have recourse to any external standard. As regards a scale of equal parts, the lecturer made use of a converse application of the law of "frequency of error," which he illustrated by many experiments, and which showed that in a row (say as before) of nuts, if we took those which occupied the three quarterly divisions (1st quarter, centre, 3rd quarter) as the three elementary graduations of size, a range of successive graduations would be obtained by the following series, in which the places of the nuts are supposed to be reckoned from the end of the row where the large nuts are situated, and to be given in per-thousandths of the entire length of the row. It might be called the "Common Statistical Scale" (S. S.). The place of $+ 4°$ would be at 4 thousandths from large end; $+ 3°$, at 21 thousandths; $+ 2°$ at 89; $+ 1$, at 250; $0°$ at 500; $- 1°$ at 750; $- 2°$ at 911; $- 3°$ at 979; and $- 4°$ at 996, or 4 thousandths from the small end of the row. Thus if we say that the size of a nut is $+ 2°$ S. S., we absolutely define it. Anybody can procure such a nut independently by getting a quart of nuts and arranging them. Also we know that the difference between a nut of $+ 4°$ S. S. and $+ 1°$ S.S. is 3°, and therefore three times as great as between one of $+ 2°$ S. S. and the latter. It cannot be affirmed that this is a precise scale of equal parts for all qualities, but it is found to hold surprisingly well in a great variety of vital statistics; perhaps, too, the mere thickness of tissues may be a chief element in the physical basis of life. This scale appears, at all events, more likely to be nearly approximative to one of equal parts, for qualities generally, than any other that can be specified, and it certainly affords definite standards subject to the law of statistical constancy. The habit should therefore be encouraged in biographies, of giving copious illustrations which tend to rank a man among his contemporaries, in respect to every quality that is discussed, in order to give data for appraising those qualities in terms of the Statistical Scale. By the general use of a system of measurement like the above, social and political science would be greatly raised in precision.

Regarding education, the lecturer disavowed speaking of what might be suitable for boys generally, but he summarised the replies of the scientific men with reference to their own special experience, and notwithstanding the diversity of branches of science, he found unanimity in their replies. They commonly expressed a hatred of grammar and classics, the old-fashioned system of education being utterly distasteful to them. The following seems the programme they themselves would have most liked:—1. Mathematics, rigorously taught up to their capacity, and copiously illustrated and applied, so as to throw as much interest into its pursuit as possible. 2. Logic. 3. Some branch of science (observation, theory, and experiment), some boys taking one branch and some another, to insure variety of interests under the same roof. 4. Accurate drawing of objects connected with that branch of science. 5. Mechanical handiwork. All these to be rigorously taught. The following not to be taught rigorously: reading good books (not trashy ones) in literature, history, and art. A moderate knowledge of the more useful languages taught in the easiest way, probably by going abroad in vacations. It is abundantly evident that the leading men of science have not been made by much or regular teaching. They craved for variety. Those who had it, praised it; and those who had it not, concurred in regretting it. There were none who had the old-fashioned high-and-dry education who were satisfied with it. Those who came from the greater schools usually did nothing there, and have abused the system heartily.

INFLUENCE OF GEOLOGICAL CHANGES ON THE EARTH'S ROTATION

AT the annual meeting of the Geological Society of Glasgow, on Feb. 12, the president, Sir William Thomson, F.R.S., gave an address on the above subject, of which the following is an abstract:—

He first briefly considered the rotation of rigid bodies in general, defining a principal axis of rotation as one for which the centrifugal forces balance while the body rotates around it. He then took the case of the earth; and, having pointed out the position of its present axis, showed that if from any cause it were made to revolve round any other, that would be an "instantaneous axis," changing every instant, and travelling through the solid, from west to east, in a period of 296 days round the principal axis It would shift continually in the figure, owing to the varying centrifugal force of two opposite portions of the body. This would produce, by centrifugal force, a tide of peculiar distribution over the ocean, having 296 days for period. An inclination of the axis of instantaneous rotation to principal axis of 1″, or 100 ft. at the earth's surface, would produce rise and fall of water in 45° latitude, where the effect is greatest, amounting to ·17 of a foot above and below mean level.

He noticed, in passing, the application of these dynamical principles to the attraction which the sun and moon exercise on the protuberant parts of the earth, tending to bring the plane of the earth's equator into coincidence with the ecliptic. This causes an incessant change, to a certain limited extent, in the position of the axis of rotation, thereby occasioning what is known as the "precession of the equinoxes." Having illustrated these remarks by some interesting experiments, Sir William Thomson proceeded to consider more particularly the circumstances according to which the axis of the earth might become changed through geological influences, and the consequences of any such change. The possibility of such a change had been adduced to account for the great differences in climate which can be shown to have obtained at different periods in the same portion of the earth's surface. In the British Isles, for example, and in many other countries, there is clear evidence that at a comparatively recent period a very cold climate—much colder than at present—prevailed; while in the same places the remains of plants and animals belonging to several preceding eras indicate a high temperature and a comparatively tropical climate. The question arose, can changes in the earth's axis account for these changes of climate? In the present condition of the earth, any change in the axis of rotation could not be permanent, because the instantaneous axis would travel round the principal axis of the solid in a period of 296 days, as already stated. Maxwell had pointed out that this shifting of the instantaneous axis in the solid would constitute in its period a periodic variation everywhere of "latitude," ranging above and below the mean value, to an extent equal to the angular deviation of the instantaneous axis of rotation from the principal axis; and, by comparing observations of the altitude of the Pole-star during three years at Greenwich, had concluded that there may possibly be as much as ½″ of such deviation, but not more.

In very early geologic ages, if we suppose the earth to have been plastic, the yielding of the surface might have made the new axis a principal axis. But certain it is that the earth at present is so rigid that no such change is possible. The precession of the equinoxes shows that the earth at present moves as a rigid body; and during the whole period of geologic history, or while it has been inhabited by plants and animals, it has been practically rigid. Changes of climate, then, have not been produced by changes of the axis of the earth. The learned professor then inquired what influences great subsidences or

great elevations in different parts of the earth might have on the axis of rotation. No doubt the removal of a large quantity of solid matter from one part of the globe to another would sensibly alter the principal axis, as well as the axis of rotation, which so nearly coincides with it; but it could be shown that it would produce in the latter only about 1-300th part of the change produced in the former. We know too little of the changes in the interior of the earth accompanying such changes on its surface to be able to state results with certainty. But he estimated that an elevation, for example, of 600 feet on a tract of the earth's surface 1,000 miles square and 10 miles in thickness would only alter the position of the principal axis by *one-third of a second*, or 34 feet. He called attention to the effect of tidal friction and subterranean viscosity in reducing any such deviation, and pointed out that it must be exceedingly slow; using for evidence the observationally proved slowness of the diminution of the earth's rotational velocity, and of the inclination of its equator to the ecliptic. It therefore seemed probable that geological changes had not produced any perceptible change in the principal axis or in the axis of rotation within the period of geological history.

OBSERVATIONS OF MAXIMUM AND MINIMUM SEA-TEMPERATURES BY CONTINUOUS IMMERSION

WHEN the Scotch Meteorological Society was instituted, now nearly twenty years ago, observations on sea-temperature were set on foot at the suggestion of the late Prof. Fleming, and have since been continued. These observations were made by the immersion of thermometers with small cisterns attached, and were taken at the surface and at a depth of 6 feet. Besides these, special observations were made for me on the temperature of the flood and ebb tide at depths extending to 50 feet in the Pentland Frith,* and hourly observations continued at intervals during four years ending in 1863 by Capt. Thomas, R.N., at depths extending to 60 feet.† Such occasional observations seemed to me to be insufficient to show properly the changes in temperature to which the sea is subject, and in August 1872 I suggested to my friend, Prof. Wyville Thomson, the propriety of ascertaining, on his exploring voyage, maximum and minimum temperatures by means of thermometers constantly immersed in the sea. For this purpose a thin malleable iron plate of an oval shape, as shown in Fig. 1, is fixed to the outside skin of the ship so as to form a small cell into which the sea-water finds ready ingress through numerous perforations. This cell, which need not project more than two inches, so as not to cause any appreciable obstruction to the speed of the vessel, should extend so far under the smooth water level as to prevent its lower end from rising above the trough of the sea, or an upright pipe might be placed within the vessel. In sailing ships there might be a cell on each side so as to secure constant immersion while the ship "is on a wind." In this cell a frame carrying a maximum and minimum thermometer slides in checks so as to be capable of being raised above water to the level of the cabin or the deck, where there should be a porthole to admit of the instruments being read and the indices being re-adjusted.

An arrangement similar in principle to that described was made in the *Challenger* exploring vessel before she left on her voyage.

In this way, during the whole of an over-sea voyage, regular observations of maxima and minima may be obtained as often as may be desired. This arrangement is peculiarly suitable to floating lights, and the Scotch Meteorological Society have been in correspondence with the Mersey Board in order to establish observations at the North-West Lightship.

The Marquis of Tweeddale in 1872 proposed that the Scotch Meteorological Society should enter upon the investigation of the migrations of fishes, and particularly those of the herring, in connection with sea-temperatures and weather generally, and his Lordship informed me that in his opinion it was likely that the herrings followed belts of water of a higher temperature than that of the sea generally.

In carrying out his Lordship's suggestion the Society has been favoured through the courtesy of the Fishery Board with returns of the daily catch of herrings and of the weather from the different fishing districts of Scotland for the last two years; and already two elaborate reports on the subject have been drawn up by Mr. Buchan, the Secretary, and published, which give good ground to hope that some positive results of considerable importance will be obtained. With reference to this investigation, I suggested, for piers and harbours, the adoption of a cast-iron pipe for containing the thermometer as shown in Fig. 2, and application was accordingly made to the Trustees of Peterhead harbour, where observations by continuous immersion have been made by Mr. William Boyd, F.R.S.E., since May 1873. It is to be regretted that these observations have in the meantime been stopped, owing to a ship having come in contact with the pipe.

FIG. 1.

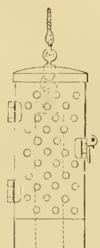


FIG. 3.

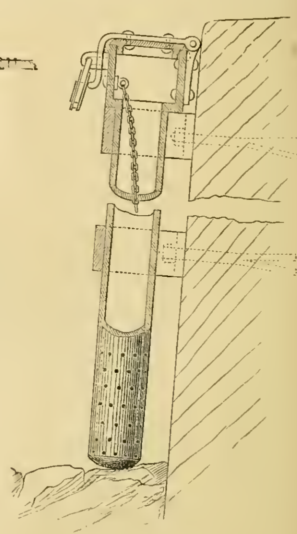

FIG. 2.

In addition to observations near the surface at floating lights, it would be extremely desirable to have thermometers immersed at greater depths, and for this purpose a copper vessel weighted below should be used, as represented in Fig. 3, with perforations in the upper part and a cistern about 4 in. deep in the lower part. The Scotch Meteorological Society, at its meeting on February 9 last, authorized an application to the different lighthouse authorities for sanctioning these deep-water observations as well as those of the surface and of the air.

OZONE*

I.

TOWARDS the end of the last century, Van Marum, while experimenting with his powerful electrical machine, observed that oxygen gas through which electrical sparks had been passed acquired a peculiar odour and the property of attacking mercury. This subject attracted no further attention for upwards of half a century after the publication of Van Marum's observations.

The discovery of ozone was announced by Schönbein in a memoir which he presented in 1840 to the Academy of Munich. In this important communication he states that in the electrolysis of water, an odorous substance accompanies the oxygen evolved at the positive pole, that this substance may be preserved for a long time in well-closed vessels, and that its production is influenced by the nature of the metal which serves as the pole, by the chemical properties of the electrolytic fluid, and by the temperature of that fluid, as well as of the electrode. The same body he found to be produced by holding a strip of platinum or gold near the knob of the prime conductor of an electrical machine in good order. With great sagacity he recognised the identity of the peculiar odour which accompanies a flash of lightning with that of the new substance. In this memoir Schönbein supposes the odorous body, for which, in a note at

FIG. 2.

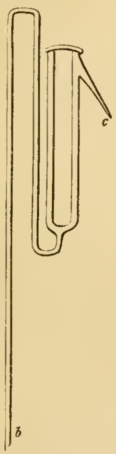

FIG. 1

the end, he proposes the name of ozone, to be a new electro-negative element belonging to the same class as chlorine and bromine; but in a paper published a little later he hints that ozone may be one of the constituents of nitrogen.

Schönbein soon afterwards discovered that ozone is formed when phosphorus oxidises slowly in moist air or oxygen.

In the following year, he returned to the consideration of the subject, and partly from his own observations, partly from experiments communicated to him by De la Rive and Marignac, he abandoned his former view of the nature of ozone, and concluded that it is an oxide of hydrogen different from the peroxide of hydrogen of Thénard.

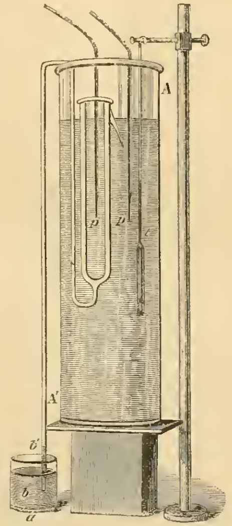
Many of the properties of ozone described by Schönbein were soon afterwards verified by Marignac, who found, as Schönbein had already stated, that it is only in the presence of moisture that air or oxygen when passed over phosphorus produces ozone, and that no ozone can be formed from air, even if moist, which has been deprived of its oxygen. He also confirmed the observations of Schönbein that the peculiar properties of ozone disappear when it is heated to a temperature between 300° C. and 400° C., and that it is not absorbed by water or sulphuric acid.

* An Address delivered before the Royal Society of Edinburgh on December 22, 1873, by Dr. Andrews, LL.D., F.R.S., Honorary Fellow of the Royal Society of Edinburgh.

In a subsequent investigation (1845) which Marignac conducted with De la Rive, the important fact was established that ozone is formed by the passage of electrical sparks through pure and dry oxygen gas. Frémy and Becquerel also showed that pure oxygen contained in a tube inverted over a solution of iodide of potassium is entirely absorbed by that liquid, if electrical sparks are passed for a sufficiently long time through the gas.

The last hypothesis of Schönbein, according to which ozone is an oxide of hydrogen, was manifestly inconsistent with the production of that body by the passage of electrical sparks through pure and dry oxygen. On the other hand, it received support from some experimental inquiries which appeared about this time, and particularly from an elaborate investigation which was conducted by Baumert in the laboratory of the University of Heidelberg, and published in *Poggendorff's Annalen* for 1853. Baumert maintained that water is always formed when dry ozone, prepared by electrolysis, is destroyed or decomposed by heat, and further endeavoured to establish its composition by determining the increase of weight of a solution of iodide of potassium when it is decomposed by ozone. He inferred, as the result of his researches, that two distinct bodies had been confounded

FIG. 3



under the name of ozone; (1) allotropic oxygen, formed by the passage of the electrical spark through oxygen; and (2) a teroxide of hydrogen, produced in the electrolysis of water. The experiments and conclusions of Baumert attracted a great deal of attention at the time they were published, and received very general assent.

Having repeated, soon after it was announced, the experiment of Baumert, in which ozone prepared by electrolysis was destroyed by heat, and having failed to obtain the slightest trace of water in numerous trials, I deemed it important to undertake a careful investigation of the subject, the results of which were communicated in 1853 to the Royal Society of London. By employing an acidulated solution of iodide of potassium, I found that its increase of weight, when decomposed by ozone, exactly agreed with the weight of the ozone calculated as allotropic oxygen from the iodine set free. The numbers deduced from five careful experiments were 0·1179 grammes for the increase in weight of the solution, and 0·1178 grammes for the calculated weight of the oxygen. As regards the supposed formation of water in the destruction of ozone by heat, it may be sufficient to mention the results of two experiments performed with great care, in one of which 6·8 litres of electrolytic oxygen containing

27 milligrammes of ozone, and in the other 9·6 litres of the same gas containing 38 milligrammes of ozone, were exposed to the action of heat, so as to destroy all ozone reactions, when not a trace of water was obtained; the increase in weight of the desiccating apparatus being in the first case only one-third, and in the second one-half, of a milligramme. If Baumert's experiments had been correct, 24 milligrammes of water should have been formed in these experiments. The general conclusions at which I arrived were: "that no *gaseous* compound, having the composition of a peroxide of hydrogen, is formed during the electrolysis of water, and that *ozone from whatever source derived is one and the same body, having identical properties and the same constitution, and is not a compound body, but oxygen in an altered or allotropic condition*." ("Phil. Transactions" for 1856, p. 13.)

The next step in the investigation of this singular body was the discovery that oxygen gas in changing into ozone diminishes in volume, or becomes condensed, recovering its original volume when the ozone is changed back into oxygen by the action of heat or otherwise. This relation between ordinary oxygen and ozone was first announced in 1860 by Prof. Tait and myself in a communication to the Royal Society of London. Oxygen gas in a dry and pure state was introduced into a tube sealed at one end and terminating at the other in a fine tube bent as shown in Fig. 1, and containing a short column of sulphuric acid. Two platinum wires were hermetically sealed into the sides of the wide tube, the distance of the ends within the tube being about 20 millimetres.

When an electrical discharge without visible sparks was passed between the extremities of the platinum wires, the sulphuric acid rose in the adjacent leg of the U-tube, and from the change of level the amount of the condensation, or diminution of volume, which the oxygen had undergone was easily calculated. The apparatus was then hermetically sealed and the reservoir heated to 270° C., so as to destroy the ozone. After allowing the reservoir to cool, the sealed end of the U-tube was opened, when the original volume of the gas was found to be restored. Strong electrical sparks were found to give scarcely one-fourth of the contraction which occurred with the silent discharge, and if sparks were passed through the gas when fully contracted by the silent discharge, the contraction was reduced to that which the spark would have produced in the original gas. In the same paper it was shown that no further diminution of volume occurred when the contracted gas was agitated with a solution of iodide of potassium so as to absorb the ozone. A similar result was obtained on agitating the contracted gas with iodine. The ozone reactions in all these cases disappeared, but without any change in the volume of the gas. With mercury and silver, not only was there no contraction, but expansion actually occurred, which was explained on the assumption that the oxide at first formed exercised a catalytic action on part of the ozone and restored it to the state of ordinary oxygen. Similar results were obtained with electrolytic ozone. Three years later these experiments on the condensation of oxygen in changing into ozone, and on the action of ozone upon a solution of iodide of potassium were repeated and confirmed by Von Babo and by Von Babo and Claus.

We did not attempt to give any absolute explanation of these singular facts; but discussed them under different aspects. We showed that on the allotropic view of the constitution of ozone its density must be enormously great; unless it was assumed that "when ozone comes into contact with such substances as iodine, or a solution of iodide of potassium, one portion of it, retaining the gaseous form, is changed back into common oxygen, while the remainder enters into combination, and that these are so related to one another that the expansion due to the former is exactly equal to the contraction arising from the latter." On this assumption, which however we did not consider probable, we remarked that "our experiments may be reconciled with the allotropic view, and an ordinary density, but still one greater than that of oxygen." A similar explanation of our experiments but connected with a peculiar view of the molecular constitution of oxygen was proposed in 1861 by Dr. Odling. "If we consider," he remarks, "ozone to be a compound of oxygen with oxygen and the contraction to be consequent upon their combination, then if one portion of this combined or concentrated oxygen were absorbed by the reagent, the other portion would be set free, and by its liberation might expand to the volume of the whole; thus, if we suppose three volumes of oxygen to be condensed by their mutual combination into two volumes, then on absorbing one-third of this combined oxygen by mercury, the remaining two-thirds would be set free and consequently expand to their normal bulk, or two volumes—

$$\overset{-}{O}\,\overset{+}{O}\,\overset{-}{O} + \overset{+}{Hg^2} = \overset{+}{Hg^2}\overset{-}{O} + \overset{+}{O}\,\overset{-}{O}."$$

Soret, experimenting in 1866 upon the mixture of oxygen and ozone obtained by electrolysis, made the important discovery, that if this mixture is brought into contact with oil of turpentine, or oil of cinnamon, a diminution of volume takes place, equal in amount to twice the augmentation of volume which the same mixture would sustain if the ozone were converted by heat into ordinary oxygen. In other words the volume of ozone, measured by its absorption by the essential oil, is twice as great as the difference between the volume of the same ozone and oxygen. Hence Soret concluded that the density of ozone is one and a half times that of oxygen gas.

The latest investigations on this subject are due to Meissner and Brodie. The former has fully confirmed my early experiments, according to which the increase in weight of an acid solution of iodide of potassium, when electrolytic ozone is passed through it, corresponds exactly to the weight of oxygen absorbed, as calculated from the liberated iodine. Meissner has also found, as I had long before stated, that when a neutral solution of iodide of potassium is employed, the results are variable and untrustworthy.

Brodie has examined the action of ozone on a variety of liquids, and has confirmed the results of Prof. Tait and myself that no diminution of volume occurs when ozone is removed from a mixture of ozone and oxygen by a solution of iodide of potassium. With other liquids he has obtained volumetric results which he considers to be definite and which differ from any previously observed. I am inclined to think that they are rather complex cases, involving the volumetrical changes already known in variable proportions. His experimental results, moreover, when examined in detail, do not appear to be sufficiently concordant to justify the sharp conclusions he has deduced from them.

Brodie has obtained for ozone prepared by the electrical discharge the same density (one and a half times that of oxygen) which Soret had previously obtained for ozone prepared by electrolysis. He considers a suggestion of Prof. Tait and myself, that oxygen may possibly be decomposed by the electrical discharge, not to be supported by the facts he has observed.

I will now give a brief statement of the methods of preparing ozone and of its leading properties.

Ozone may be obtained by the action of the electrical spark, or the glow or silent discharge on pure oxygen. With the silent discharge, as has been before stated, at least four times as large an amount of ozone is obtained as with the spark. As regards the actual amount of oxygen which, under the most favourable conditions can be converted into ozone, the highest recorded result was obtained in an experiment by Prof. Tait and myself, in which a contraction of one-twelfth of the original volume of the oxygen, or 8·3 per cent., occurred; but we were unable in other trials to produce again so great a diminution of volume. The greatest contraction attained in the experiments of Von Babo and Claus amounted to 5·74, and in those of Brodie to 6·52 per cent. The doubt which existed as to the accuracy of our solitary experiment I have lately been able to remove, and by a slight modification in the form of the apparatus I have succeeded in obtaining greater contractions than any hitherto recorded. In one of the first trials the diminution of volume amounted to more than 10 per cent., and there can be little doubt that with care even greater contractions than this may be attained.

As the method referred to enables the contraction of oxygen in changing into ozone to be exhibited as a class experiment, I will describe it in some detail. The excellent induction tube of Siemens, in which the electrical discharge from an induction coil acts upon air or oxygen, as it flows between two thin tubes of glass, whose surfaces are at a distance of a few millimetres from one another, has hitherto been employed to obtain a continuous stream of ozone in a more or less concentrated state. But this apparatus can easily be modified so as to show the contraction which takes place when oxygen is converted into ozone. Fig. 2 exhibits the modification I have given for this purpose to the ordinary form of Siemens' tube. At *c* it terminates in a capillary tube, the end of which is hermetically sealed, after a stream of pure and dry oxygen gas has been passed through the apparatus for a sufficient time to displace the air. In exact experiments the other end (*b*) is at the same time sealed and afterwards opened under sulphuric acid. For class purposes it will

be found sufficient to immerse it quickly under the acid, contained in the beaker (*a*), as shown in Fig. 3, where the induction-tube is seen immersed to within 12 millimetres of its upper surface in water contained in an *insulated* cylindrical vessel (A A′). The inner cavity of the induction-tube is also filled with water to about the same level. By means of wires covered with caoutchouc, except at the lower ends (*p p′*), the discharge from an induction-coil, capable of giving 10 millimetre sparks in air, can be passed through the apparatus. The water in A A′ is maintained as steadily as possible at the temperature of the apartment, and any slight changes in the course of the experiment are noted by means of a delicate thermometer (*t*). The variations of the barometer are also carefully observed. In very exact experiments the surfaces of the induction-tube should be covered with tinfoil, and the cylindrical vessel filled with ice. Before commencing the observation, it will be found convenient, if the temperature has not already effected the adjustment, to expel a little oxygen from the induction-tube, so that the level of the acid may stand somewhere about *b′*. On passing the electrical discharge, the acid will at first be depressed a few millimetres, from the repulsive action of the particles of the electrified gas, but will afterwards steadily rise, and for some time with such rapidity that the ascent of the acid column can be easily followed by the eye. When the current is interrupted, a sudden rise of the acid column will occur equal to the depression which took place on first making connection with the induction coil, after which the new level of the acid may be read.

Another method of obtaining ozone is by the electrolysis of water and of certain acid and saline solutions. The most convenient liquid for this purpose is a mixture of one part of sulphuric acid with six or eight parts of water, and the lower the temperature at which the electrolyte is maintained during the process the greater is the amount of ozone. The simplest and most efficacious arrangement for obtaining ozone by this method is one I have used for many years and exhibited in my lectures. It consists

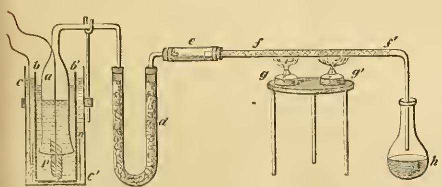


Fig. .

of a bell-jar (Fig. 4, *a*), or glass cylindrical vessel, open below, and contracted to a neck above, which is suspended in a round cell (*b b′*) of porous earthenware, leaving a clear space of two inches between its lower edge and the bottom of the porous cell. The whole is placed in a glass jar (*c c′*) of somewhat larger dimensions than the cell; a bundle of platinum wires (*p*) suspended below the bell-jar serves as the positive pole, and a broad ribbon of platinum (*n n′*) placed between the outer glass jar and the porous cell as the negative pole of a voltaic arrangement of three or four couples. A delivery tube hermetically united to the neck of the bell-jar conveys the mixture of oxygen and ozone disengaged at the positive pole to a sulphuric acid drying tube (*d*). From the desiccating tube the gas passes through the connecting tube (*e*) and thence to other tubes, for the purpose of illustrating the properties of ozone. Thus, in the figure, it is represented as traversing a tube of hard glass (*f f′*) covered with fine wire gauze, and terminating near the surface of mercury contained in the flask (*h*). So long as the gas is heated strongly as it passes through the tubes (*f f′*) by the spirit lamps (*g g′*), not the slightest change is produced upon the mercury; but when the lamps are removed, and the tube allowed to cool, the mercury is rapidly attacked. I ought, perhaps, to mention that all the junctions are made with dry and tightly fitting corks, care being taken that the ends of the connecting tubes project a little beyond the corks. With these precautions the loss of ozone, from its action on the corks, is altogether insignificant.

Ozone can also be obtained by the slow oxidation of phosphorus, and of certain ethers and essential oils in presence of moisture.

(*To be continued.*)

NOTES

One of the last and one of the best acts of the late Government was to grant a pension of 150*l.* a year on the Civil List to Prof. Sharpey. Dr. Sharpey has done as much as any living teacher for the advancement of physiological knowledge, while his personal worth has secured for him universal respect and esteem.

At the last monthly meeting of the Russian Imperial Geographical Society M. Venioukoff, the secretary, before proceeding with the business of the evening, said the Society owed a duty which must first be fulfilled, and that was to render homage to the memory of Dr. Livingstone, the importance of whose discoveries and the perseverance of whose labours had placed him in the rank of the most remarkable travellers of all times and of all nations. His biography belonged to the annals of geographical science. M. Venioukoff then read a memoir of Livingstone, which concluded as follows:—"Let England, which may be proud of having given birth to Livingstone, and of having supported him in his labours, learn that among us the merit of her great men can be appreciated." The whole assembly, which was very large, then rose in order to pay a last tribute of respect to the memory of Dr. Livingstone.

The University of St. Andrew's has conferred upon Mr. J. Gwyn Jeffreys, F.R.S., the honorary degree of LL.D.

We would draw special attention to the programme, which has just been issued, of a new course of twelve lectures on Zoology, to be delivered during the ensuing spring, in the Zoological Gardens, Regent's Park; the Council of the Society having determined to appropriate the interest of a small bequest which they hold for scientific purposes—the Davis Fund—to the subject. Mr. P. L. Sclater, F.R.S., the Secretary to the Society, will deliver the Introductory Address on April 14; and he will follow it by four lectures *On the Geographical Distribution of Mammals.* After these Mr. A. H. Garrod, the Prosector to the Society, will give five lectures *On the General Classification of the Vertebrata;* and Dr. Carpenter, F.R.S., will conclude the course by giving two *On the Aquarium and its Inhabitants.* The lectures will be delivered on the Tuesdays and Fridays in April and May, at 5 o'clock in the afternoon; they will be free to Fellows of the Society and their friends, and to other visitors to the Gardens. The subjects will be treated in a manner which will make them of general interest, and it is to be hoped that ladies will avail themselves of the opportunity thus afforded, of obtaining information on this too much neglected branch of the great science of Biology.

Mr. Philip Barnes, who died on Feb. 24, at the age of 82, was one of the oldest Fellows of the Linnean Society. He was a native of Norwich, and a cousin of the Sowerbys. Thirty-four years ago he founded the Royal Botanic Gardens in the Regent's Park, and was the oldest Fellow and father of the Society. A portrait of Mr. Barnes was in the last International Exhibition, and a bust in that of the year before. He was father of Robert Barnes, M.D., and of the late Philip Edward Barnes, the former known in the scientific world by his professional discoveries and writings, and the latter the author of a work on the Belgian Constitution.

The death, from heart-disease, of Prof. J. F. Holton is announced as having taken place in Everett, Massachusetts, U.S., on the 25th of January. Prof. Holton was well known as a botanist, having devoted many years to the study of the science. He visited South America with special reference to prosecuting his researches in this direction, and studying the relation between the physical geography and the vegetation of the Andes. His somewhat extended sojourn in that country enabled him to collect materials for a work, which was published after his return by Harper and Brothers, and is frequently quoted by botanists.

MR. WILLIAM DUNVILLE has presented a valuable endowment in trust for ever to the Queen's College, at Belfast. The endowment consists of two studentships, one for the encouragement of the mathematical and physical and the other for that of natural sciences. They are intended by the donor to enable distinguished students who attained graduation to pursue their collegiate studies further. The studentships are tenable for two years, and are of the value of 45*l*. for the first, and 100*l*. for the second year.

WE hear from Cambridge, Massachusetts, that the chair of Zoology held by Professor Agassiz during his lifetime is most probably to be discontinued, and that the teaching he was accustomed to give will, for some time at least, be carried on by Prof. McCrady and Prof. Shaler. Mr. Alexander Agassiz is to be Curator of the Museum, which post being very onerous, prevents him from accepting any professorial work. The new Zoological School at Penikese is also to be under his charge, and we hope that that promising institution will be kept up with vigour notwithstanding the great loss it has sustained in the death of its illustrious founder.

WE learn from the *Lancet* that a memorial to Agassiz is in contemplation. At Boston a meeting for the purpose was addressed by Profs. Rogers and Wendell Holmes, after which it was resolved to make the Museum of Zoology at Cambridge—the work of Agassiz's best years—a memorial monument. For this it was proposed to raise the sum of 300,000 dols. to complete its endowment. 65,000 dols. were subscribed before the proceedings closed.

THE first part of a new Russian work by M. Prijevalsky, entitled "Mongolia and the country of the Tanguts," may be expected before the end of the year. It will contain an account of the author's travels in Central Asia, together with a description of the Zoological and Botanical results he has arrived at. In all, 64 species of mammalia, and 292 species of birds were obtained, including among the most remarkable of the former, the Wild Yak, the Orongo Antelope and *Ovis polii*; of the latter *Gyps nivicula* and a new species of *Pterorhinus*. The botanical collection includes, according to the botanist Maczimovitch, a great many new and rare specimens. In the mountains of Kansu about 500 different plants were obtained, including the seeds of the medicinal rhubarb.

THE Cambridge Syndicate appointed to organise courses of lectures or classes with the necessary examinations in a limited number of centres of population have received applications from several places to supply teachers during the ensuing winter. Among the subjects suggested for choice are Political Economy, Mental and Moral Science, History, English Literature, Physiology, Physical Geography, Geology, Astronomy, Mechanics, various branches of Physical Science, and other subjects of a kindred character to these. The remuneration offered varies from 125*l*. to 200*l*. for the term of three months, there being two such terms to be provided for between October and May. The pupils [illegible] chiefly from among young men and women of the middle and working classes. The Syndicate request any gentleman willing to take part in such work to send his name and the statement of subjects he would be willing to give instruction in to Mr. Stuart, M.A., Trinity College, the secretary.

THE Council of the Senate of Cambridge University recommend that a Demonstrator of Experimental Physics be appointed at an annual stipend of 150*l*. The duties of such person shall consist of assisting the Professor in giving class instruction and making experiments. He is to be appointed by the Professor, with the consent of the Vice-Chancellor. A discussion of this report takes place to-day.

M. J. PLATEAU has recently published, in two volumes, a work entitled "Statique expérimentale et théorique des liquides soumis aux seules forces moléculaires" (London: Trübner). M. Plateau has effected the realisation, on a large scale, of a part of the figures of equilibrium, indefinite in number, which would affect liquids if gravity did not act upon them; he has thus furnished the experimental verification of a series of results obtained by geometers in respect to surfaces whose mean curvature is constant, such surfaces as those of figures of equilibrium. The work referred to contains an account of the author's researches on the forms and phenomena presented by liquids in the condition named, as well as the consequences which result therefrom. The following are two examples of these consequences:—1. The froth which is formed on champagne and other liquids is evidently an assemblage of laminæ, which enclose in their interstices small portions of gas. One might naturally expect that in this assemblage all would be ruled by chance, but it is nothing of the kind; the small laminæ never unite but three and three, and make with each other, at the small liquid edge which unites them, equal angles of 120°. Moreover, the liquid edges throughout unite four and four, and thus form between them, at the point where they meet, equal angles, angles whose cosine is $-\frac{1}{3}$. 2. The beautiful observations of Savart have taught us that a vein of liquid pierced by a circular orifice is gradually converted, during the passage of the liquid composing it, into a series of isolated masses. The illustrious French physicist, to account for this phenomenon, has tried to prove that the very act of flowing gives rise, in the orifice, to pulsations which produce in the vein successive protuberances, and this hypothesis has been adopted by most of the students who have inquired into the matter. M. Plateau shows that this ingenious notion is quite insufficient to account for the facts, that the conversion into isolated masses is a result of the molecular forces which are in action at the surface of the vein, and that from this naturally result all the particulars established by Savart.

SCIENCE seems likely to be treated royally in Sweden this year. For the expenses of the Congress of Archæology and Prehistoric Anthropology, which will be held at Stockholm from Aug. 7th to 16th, the Government has asked from the Diet a grant of 20,000 fr.; a magnificent palace has been set apart for the holding of the congress; two grand fêtes will be given by the king and by the city; and visitors will be carried by the railways at half-fares. The programme includes papers and discussions on the stone age, bronze age, and iron age, and on prehistoric archæology; and excursions will be made to places of archæological interest and remains of prehistoric man in the neighbourhood. The "Congrès d'archéologie slave" will also be held at Kiew, from Aug. 14 to Sept. 3. Altogether, students of prehistoric man will have a good time of it in North Europe this summer.

THE appointments to the Bureau des longitudes at Paris for 1875 are—M. Puiseux as president, M. Faye as vice-president, and M. Yvon-Villarceau as treasurer and secretary.

THE French Academy is publishing a large 4to volume of 300 pages, containing all the reports and maps relating to the next Transit of Venus. A copy has been presented to each member, and the book is to be had at M. Firmin Didot's, the publisher to the French Institute.

SOME carpenters are at present engaged in building in the Jardin de Luxembourg at Paris a photographic studio, for the use of the photographers who are to be sent out with the Transit expedition. The observations are soon to begin, and will be under the direction of M. Fizeau, member of the French Institute; but that gentleman will not leave Paris to follow the operations.

THE young King of Siam having come of age on October 10 last, great feasts were given to his subjects at Bangkok, the chief town of his dominion. Amongst other attractions was the ascent of a small mounted balloon, which had been constructed in Paris and had arrived by steam a few days previously.

Liberal offers were made to procure an aëronaut, but were of no avail, nobody amongst the Siamese presuming to ascend. Consequently his Majesty ordered a slave, selected from amongst the less heavy of his household, to be sent up in the car. In order to encourage the poor aëronaut, so frightened for his life, he was promised to be rewarded with his enfranchisement. The ascent took place and elicited much enthusiasm from the bystanders; but, unhappily, nothing was heard from the poor fellow or of the craft.

THE Universal Exhibition to be held in the Champs Élysées Palace in 1875 is merely a private enterprise; the French Government having no intention to interfere except in giving its authorisation. No charge will be made on the national Exchequer, but it is rumoured and hoped that the Municipal Council of Paris will grant a considerable sum of money.

MR. G. J. SYMONS writes to yesterday's *Times* suggesting various methods, all good, and we think practicable, of distributing daily, or even at certain intervals during each day, the accurate time throughout London. This is an advantage possessed for long by many provincial towns; though London in this, as in many other respects, is far more "provincial" than many a second-rate provincial town. We are glad to see, however, from Mr. W. Abbott's letter in the same paper, that the want complained of by Mr. Symons will soon, to some extent, be remedied; as one of the objects of the British Telegraph Manufactory (Limited), which has just taken over all the inventions of Sir Charles Wheatstone, is to establish a large electrical driving clock in a central position of the metropolis.

THE Commissioners of the Fairmount Park, Philadelphia, U.S., are making great efforts in the way of bringing together, in the form of a zoological garden, a complete collection of animals of North America, with a view of their exhibition at the approaching Centennial Exhibition. The Commissioners are also expecting considerable consignments from other parts of the world, as South Africa, South America, &c., and the whole enterprise bids fair to assume a very great magnitude.

AT a meeting of the California Academy of Sciences in November last, photographs of strange but beautiful hieroglyphics, cut in wood, and found on Easter Island, were received from Mr. Thomas Croft, of Papeeti, Tahiti. From vague traditions among the natives, they were supposed to represent the written language of some prehistoric nation. The stone idols found on the island exhibit a refined form of art, and other relics found there go to prove that the present population has gradually degenerated from a previous one. In the letter accompanying the hieroglyphics, Mr. Croft stated from the best information he could obtain, that none except the priests and a chosen few could decipher these strange characters. A letter was read from this gentleman at the last meeting, in which he stated that he had found a native of the island who could read them, and who was going to teach Mr. Croft the language, so that he will shortly be able to translate them. Mr. Croft thinks that he has discovered the relics of a great Malayan empire, which extended its power over that part of the ocean at some former period of the island's history.

"THE Treasury of Languages, a Rudimentary Dictionary of Universal Philology" (London: Hall and Co.), is an attempt at making an exhaustive alphabetical list, with brief explanations, of all the known languages and dialects of the world. It contains, besides, explanations of terms used in the science of language. The volume contains 300 pages, with an average of fifteen names on each page; this will convey some idea of the variety of tongues on the face of the earth. The author, who is nameless, but who, we are told, is a "literary amateur," moreover intimates that he has received additional material sufficient to make a second volume. What a bewildering field is before the student of languages, to whom the present work is calculated to be extremely useful.

WE have received a second and richly illustrated edition of Mr. Hartwig's "Polar World" (Longmans). The record of Arctic discovery has been succinctly brought up to the present time, and the work is well calculated to convey to the general reader a vivid, and on the whole correct, idea of man and nature in the Arctic and Antarctic regions of the globe.

PART I. of Vol. V. of the "Natural History Transactions of Northumberland and Durham" (Williams and Norgate) has come to hand. It contains the usual Annual Address of the President, Mr. H. B. Brady, F.L.S., who recounts the excursions of 1872, and touches on one or two important questions of the day, with clearness, vigour, and brightness. The following are the titles of the papers in this part:—"Note on the recent occurrence in Northumberland and Durham, of the Camberwell Beauty Butterfly," by T. J. Bold, who also contributes papers on "The Museum Collection of British Insects," and "The Occurrence of Lepidoptera in Northumberland and Durham in 1872;" "Note on Bones dredged from the bed of the river Weir in 1872," by Dr. D. Embleton; "Meteorological Report for 1872," by the Rev. R. F. Wheeler and the Rev. Dr. R. E. Hooppell; "First Instalment of a Catalogue of the more remarkable Trees of Northumberland and Durham," by Mr. G. C. Atkinson, who has devised a "hypsometer," a simple but useful instrument for ascertaining the height of trees; "Note on Cinerary Urns found at Humbledon Hill, near Sunderland."

PART III. of Vol. III. of "Proceedings and Transactions of the Novia Scotian Institute of Natural Science," has been sent us. Besides a summary of the Proceedings of the Society, it contains twelve papers of varying value on scientific subjects, eight of these being by three of the members; this Society, like many others at home apparently, having many names on its roll but few working members. Three papers are by the Rev. Dr. Honeyman, F.G.S., Director of the Provincial Museum:—"On the Geology of Nova Scotia and Cape Breton," "On the Metamorphism of Rocks in Nova Scotia and Cape Breton," and "The History of a Boulder." Of the other papers we may mention two by Dr. J. B. Gilpin on "The Eagles of Nova Scotia," and "The Stone Age of Nova Scotia;" "The Great American Desert," by Mr. H. S. Poole; and "The Vegetation of the Bermudas," by Mr. J. M. Jones, F.L.S. Appended is a brief note on the visit of the *Challenger* to Halifax.

THE "Report of the Birmingham School Natural History Society for the year 1873," is on the whole satisfactory. All the sections seem to be in good working order, their meetings fairly attended, and some profitable field-work is being done. The papers, abstracts of which are published in the report, are creditable to the young gentlemen who wrote them.

WE have received a large sheet containing Statistical Tables relating to the Colony of Victoria, compiled from official records in the Registrar-General's Office, Melbourne, by Mr. W. H. Archer, Registrar-General. The tables contain a vast amount of information, well and compactly arranged, concerning the population, industry, education, &c., of the colony. The sheet contains also the usual meteorological statistics for the twelve months of the year, and extending over a period varying from six to fourteen years.

THE additions to the Gardens of the Zoological Society during the past week include a Common Rhea (*Rhea Americana*) from S. America, presented by Mr. A. Maxwell; a Black-tailed Godwit (*Limosa melanura*), British, presented by Mr. H. Stacy Marks; a Red-faced Deer (*Cervus œnops*) and two Falcated Teal (*Querquedula falcata*) from China, purchased; a Chinese Water Deer (*Hydropotes inermis*), a Reeves' Muntjac (*Cervulus reevesi*), and a Japanese Teal (*Querquedula formosa*) from China; a Collared Peccary (*Dicotyles tajuça*) from S. America, deposited.

SCIENTIFIC SERIALS

American Journal of Sciences and Arts, January 1874.—This number commences with an account, by Mr. H. Gillman, of some Indian mounds and skulls in Michigan. The numerous tibiæ unearthed showed the compression or flattening which characterises platycnemic men; and the race, from Detroit River to St. Clair and Lake Huron, seems to have been marked with platycnemism to an extreme hitherto unobserved in any other part of America, or perhaps any other country in the world. The writer thinks the type of bone will be found predominant in the entire region of the great lakes.—Mr. Hilgard follows with a note on silt analyses of Mississippi soils and sub-soils (the author having used his "churn elutriator"); and Mr. Longbridge discusses the distribution of soil ingredients among the sediments obtained in silt analysis, and the influence of strength of acid and time of digestion in the extraction of soils.—Mr. Lesquereux communicates the remarkable discovery that traces of land vegetation exist in the Lower Silurian of America; branches or small stems of a species referable to *Sigillaria* having been found by the Rev. H. Herzer in clay beds of the Cincinnati group. The only records hitherto had of vegetable remains from the Silurian of North America are some fragments of stems and rhizomes of *Psilophyton* observed by Dawson in the Gaspé group of Canada; the only link of connection of the Devonian flora with that of the Silurian period. In Europe, too, the first remains of land plants have been found in the Lower Devonian; and as yet only a single specimen of *Sigillaria*. The same writer, in another note, argues against the view, recently advanced, that the lignite beds of the Rocky Mountains have been formed by the heaping up of drifted materials. We also find notes on the geology of Western Texas (Jenney), on the results of recent dredging expeditions on the coast of New England (Verrill), on fossil woods of British Columbia (Dawson), on a combination of silver chloride with mercuric iodide (Lea), &c.—An appendix contains a paper (with two plates) by Prof. Marsh, treating of the structure and affinities of the Brontotheridæ.

Poggendorff's Annalen der Physik und Chemie, No. 11, 1873.—This number contains the concluding part of M. Kundt's paper on the vibrations of square air plates.—Dr. Schüngel describes some experi nents made with reference to change in the pitch of sounds through a movement of translation of the sounding body. He arranged an apparatus in which a tuning fork, mounted, with its case, on a little waggon, was rapidly drawn along (by a cord passing round a drum) towards the observer, who stood beside another fork making a slightly greater number of vibrations than the moved one. In this way a different number of beats was obtained; less than that produced when both forks were at rest. The pressure of a key, giving rise to this motion (through electro-magnets, &c.), caused a telegraphic strip of paper to be at the same time impressed, showing a continuous line; and a second pendulum, closing a current at each swing, produced a series of points on the same strip. By this means could be measured the time in which a certain number of successive beats was heard, and the rate of motion of the travelling fork. The author points out how the method may be employed for determining the velocity of sound, and commends it to the attention of physicists for further development.—M. Zöllner replies, at some length, to the considerations urged by M. Reye against his explanation of the sun-spots and protuberances; and M. Behrens communicates a note on porcelain and allied products.—A mercury air-pump, of improved construction, is described by M. Mitscherlich; and a variation-barometer by M. Kohlrausch; the latter instrument being formed with the vacuous metallic ring of a Bourdon aneroid.—M. Herwig makes a calculation of the number and weight of ether-molecules contained in electrical conductors.—Among the extracted matter, we note several important papers; one by Dr. Heinrich Streintz (Vienna Acad.), on the changes in elasticity and length of a wire traversed by a galvanic current; one by M. Plateau (Belgian Acad.) on the measurement of physical sensations, and the law which connects the intensity of these with that of the exciting cause; and one by M. Helmholtz (Berlin Acad.) on galvanic polarisation in gasless liquids.

Astronomische Nachrichten, No. 1,974.—In this number Prof. Spoerer writes a very interesting account of his sun-spot and prominence observations, from which he concludes that faculæ occupy the same places where protuberances arise or where the points of the "flaming chromosphere" are situate; and further, that protuberances are in most cases connected with spots, and are very conspicuous before and at the commencement of a group of spots. In many cases, he says, it is possible to calculate when a spot will appear, from the observation of a flaming protuberance, and that the spots are produced by the substances thrown up becoming cooled and producing a cloud of products of condensation.—Dr. Hugo Goricke contributes a number of observations of position of the minor planets Asia, Flora, Thetis, and Hera.

Astronomische Nachrichten, No. 1,975.—In this number Prof. Schmidt gives an account, in full, of his observations on Sunspots, the number of groups being given for each day in 1873, the maximum number on any one day being 9, and the minimum 1. There is no day on which the sun was free from spots. Prof. Schmidt says that clouds have prevented observations on 12 days; we, in this country, should be content with missing 120 days. Prof. Schmidt also gives the maxima and minima of a number of variable stars, and we regret that want of space prevents our reproducing his results, which are worthy of perusal by those interested in the matter.

Der Naturforscher, Jan. 1874. In this number we may first note an account of some observations by M. Hann, at Hong Kong and in Ceylon, as to the decrease of temperature with the height. It appears that the yearly average of decrease is much the same in the tropics as in central Europe. During the regular monsoons, the decrease is much more gradual on the windward side of a mountain than on the lee. The quick decrease in time of rain is due, in part, to increase in quantity of rain with the height, and greater cooling in consequence.—From experiments on alcoholic fermentation, by M. Brefeld, it is concluded that alcohol yeast always requires free oxygen for its growth; it cannot grow on oxygen from a compound like sugar; further, that living, but non-growing, yeast-cells (free oxygen being excluded) may yet excite fermentation in sugar solution. As showing the affinity of the yeast-cell for free oxygen, the author states that it may grow in CO_2 containing less than $\frac{1}{1000}$ of its volume of such gas, and will fully absorb it.—We also find a note of some experiments on butyric fermentation, by M. Paschutin; and in the botanical department there are several interesting notes.—On the reaction of plant protoplasm to mechanical injuries, by M. Hanstein; the cause of periodical motions in leaves, by M. Batalin, stated to be, chiefly, unequal growth, preponderating at one side or the other, through varying conditions of light, temperature, and turgescence; on the morphological differentiation of the lower plants, by M. Pfingsheim, and others.—In a suggestive mineralogical paper, M. Hirschwald theorises on the cohesion-relations in drops and in crystals.—Physics is represented by several extracted notes—on evaporation, on phenomena of polarisation produced through dispersion of light, on relations between capillary and electric phenomena, on intermittance of the electric current, &c., most of which have already been noticed elsewhere in our columns; and in physiology there is an account of a valuable investigation by M. Forster, as to the significance of ash-constituents in food.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, Feb. 12.—"On the influence of Ethyl Alcohol on the Bodily Temperature, the Pulse, and the Respirations of a healthy man." By E. A. Parkes, M.D., F.R.S., Professor of Hygiene, Army Medical School.

The author made a large number of experiments on a strong healthy soldier, T.R., aged twenty-five, height 5 ft. $8\frac{3}{4}$ in., weight (naked) 67·46 kilogrammes, or 148 lbs.

The course of the experiments was as follows:—His breakfast was taken at 6.30, was finished every day by 7 A.M.; he took for breakfast 8 ounces of bread, $\frac{1}{2}$ ounce of butter, and 17 fluid ounces of tea with sugar, and with 3 ounces of milk. Immediately after breakfast he went to bed again, and did not get out of the recumbent position for any purpose until 2 o'clock. He then dined on 12 ounces of beefsteak, 4 ounces of bread, and 8 ounces of water.

After dinner he took exercise and smoked, had tea (same food as at breakfast) at 6, and a glass of water at 9 P.M., when he went to bed. He took daily precisely the same diet and quantity of water.

Thermometers (tested for accuracy and exactly corresponding) were placed in the axilla and rectum at 6 o'clock, and, except

at breakfast, they were removed only for the purpose of being read at first every 30, and then every 15 minutes, and were at once replaced, until 2 o'clock; after which time the temperatures were only taken every two hours.

After several days' preliminary examination (during which time he took no alcohol) the experiments were commenced and carried on for six days without alcohol; then during five days undiluted brandy containing 50 per cent. of absolute alcohol was given once daily, viz. at 11 A.M., four hours after breakfast.

On the first day one fluid ounce of brandy (= ½ ounce of alcohol) was given; on the second day two ounces, on the third day four ounces, on the fourth day six ounces (= 3 ounces of alcohol), and on the fifth day also six ounces.

The following were the conclusions arrived at:—

1. The change in the temperature of the axilla and rectum produced by brandy was very slight. It was never increased, but was probably slightly lowered; but the result is not quite certain; and if any lowering occurred, it did not exceed 0°·35 Fahr., and may not have been more than 0°·07 Fahr.

2. The pulse, which was lessened in number by long rest in a recumbent position, was increased in frequency by a single dose of brandy for three hours, but subsequently fell in number, so that the daily work done by the heart was the same on the water and the brandy days. What occurred was accelerated work for a certain time, and compensation for this by lessened work afterwards. That brandy increases the force as well as the number of the pulse, was shown by sphygmographic tracings in the papers already communicated to the Royal Society; and in order not to disturb the state of rest, no sphygmographic observations were taken in this case.

3. The respirations appeared to be slightly lessened by brandy; but the evidence is not very strong.

The author made another series of experiments to determine the effect of alcohol after sixteen hours' fasting.

The following conclusions may be drawn from the observations formerly recorded ("Proceedings of the Royal Society," Nos. 120, 123, and 136), and from those now laid before the Royal Society:—

1. When alcohol in dietetic doses (=2 fluid ounces, or 57 cub. centims., of absolute alcohol) was given to a healthy man fasting and at rest, a decided though slight lowering of bodily temperature (as judged of by the heat of the rectum) was caused. The amount of lowering was under half a degree of Fahrenheit; and sometimes even this amount was not perceptible, being probably counteracted by the opposing influence of the heat-producing changes in the body, which cause slight variations of temperature independent of food and movement. The greatest effect was produced about from one to two hours after the alcohol was taken, and the effect was evidently passing off in three hours.

2. When alcohol in dietetic doses was given to a healthy man at rest, and in whom the process of digestion was completed, and whose temperature, raised by the food, was again commencing to fall, a lessening of temperature was also proved, but its amount was not so great; it could not have been more than 0°·35 Fahr., and may have been only 0·07 Fahr.

3. When alcohol was given with food with either usual or increased exercise, no effect on temperature was perceptible, even though the alcohol was given in large quantities, viz. from 4 to 8 fluid ounces of absolute alcohol (114 to 227 cub. centims.) in twenty-four hours. It is to be presumed that the amount of heat generated from the food and movement concealed the effect of the alcohol, which would require a more delicate method for detection.

4. In no case did alcohol raise the temperature.

5. The effect of alcohol on the pulse was uniform in the four men experimented upon. The contractions of the heart were more frequent during complete rest, from five to ten beats per minute for some time; and when exercise was taken the increase was greater. The mean pulse of the twenty-four hours was, however, not increased unless the amount of alcohol was large and repeated. In other words, the heart's beats were less frequent than natural when the effect of the alcohol had passed off. The pulse became both fuller and softer to the touch; and this relaxation of the radial artery was shown also by the sphygmograph. That the smaller vessels were relaxed was shown by the redness of the surface and by the evident ease with which the blood traversed the capillaries, as shown by the sphygmographic tracings.

6. The respirations were not increased in number by alcohol; they were indeed lessened, and were deeper in some of the experiments; but the effect was not very marked.

Feb. 26.—"The Winds of Northern India, in relation to the Temperature and Vapour-constituent of the Atmosphere," by Henry F. Blanford, F.G.S., Meteorological Reporter to the Government of Bengal.

Geological Society, Feb. 20.—His Grace the Duke of Argyll, K.T., F.R.S., president, in the chair. In handing the Wollaston Gold Medal to the foreign secretary, Mr. W. W. Smyth, for transmission to Prof. Heer, of Zurich, the president referred to the fact that last year the council had awarded the balance of the proceeds of the Murchison Geological Fund to Prof. Heer, and remarked that it gave him much pleasure that the Wollaston Medal, the highest honour which the Society had it in its power to confer, should be so worthily bestowed. He alluded briefly to the labours of Prof. Heer in the difficult departments of Fossil Botany and Entomology, and to the admirable works in which he had given to the world the results of his indefatigable researches.

Mr. W. W. Smyth, in reply, said:—"My Lord President, it is with a great pleasure that I undertake the transmission to Prof. Heer of this new testimony of the importance attached by this Society to his long-continued labours. I have received from our valued foreign member a letter stating that my announcement of the award had found him extended on the bed of sickness, and begging me to assure the Society that, but for this misfortune, nothing would have given him greater pleasure than to have been present at this meeting, and to have thanked the Society personally for the high honour which has now been awarded to him."

The President then presented the balance of the proceeds of the Wollaston Donation Fund to the foreign secretary for transmission to Dr. H. Nyst, of Brussels, remarking that this distinction had been well earned by Dr. Nyst by his admirable researches upon the Molluscan and other fossil remains of his native country.—Mr. W. W. Smyth briefly thanked the president on behalf of Dr. Nyst.

The president next presented the Murchison Medal to Dr. J. J. Bigsby, F.R.S., and remarked in so doing that there was a peculiar fitness in this award, which would have met the approval of the distinguished geologist in accordance with whose last wishes this medal was given. It was awarded to Dr. Bigsby in recognition of his long and valuable labours in that department of geology and palæontology with which the name of Murchison is more particularly connected.—Dr. Bigsby replied, thanking the Society for the honour conferred upon him, and the president for the terms in which he had spoken of his labours.

The president then handed half the balance of the proceeds of the Murchison Geological Fund to R. Etheridge, F.R.S., for transmission to Ralph Tate, F.G.S., expressing a hope that it would be regarded by him as a testimony of the value set by the Society upon his palæontological researches, especially on the Fauna of the Lias, and that it would enable him to enlarge the sphere of his investigations.—Mr. Etheridge, in reply, read the following letter of acknowledgment from Mr. Tate:—

"My Lord President and Gentlemen, To say that I am unworthy of the honour that you have awarded me by the bestowal of the 'Balance of the Proceeds of the Murchison Fund,' would be to call into question your judgment, and would render nugatory its value to me. The encouragement that such an award conveys is ample recompense for labour bestowed in palæontological research, and is a real incentive to more diligent work. It is in this spirit that I accept the award, and tender my warmest thanks to you for the distinction it confers. It is now twelve years since I was led to select for special study the geological history of the Lias, which appeared to me not to have received that attention at home that it had upon the Continent, and which it claimed by offering the earliest phase of Mesozoic life, and presenting a number of physical problems that seemed upon the threshold of the inquiry to reward even the casual observer with a rich harvest. I have published from time to time fragments relating to the stratigraphy and palæontology of this period, but I hope soon, in conjunction with my friend Mr. J. F. Blake, F.G.S., to submit, in a work entitled 'The Yorkshire Lias,' a comprehensive review of the chief characteristics of the period, embracing the remarkable variation of mineral conditions, and the particular distribution of organic life, as indicative of peculiarities of depth of ocean, the direction and proximity of land, &c. Despite all these efforts, the ambition to acquire the position of an expositor of the life of this interesting group of strata urges

me to the completion of a *Prodromus* or *Thesaurus Liassicus*, the materials for which have been accumulated during several years; but from the great labour demanded to bring into harmony the nomenclature of the fossils, without which the compilation can have no real value, some time must elapse before the results can be submitted to you.—Faithfully yours, Ralph Tate."

The President then presented to Mr. Alfred Bell the other half of the balance of the proceeds of the Murchison Geological Fund, and stated that this was awarded to him in recognition of his valuable researches upon the fossils of the newer Tertiary beds of this country, and to assist him in the completion of his work upon the Crag deposits of the eastern counties. Mr. Bell, in reply, said that he was most grateful for this token of the Society's appreciation of the value of his labours, and stated that up to the present time he had been enabled to distinguish about 3,000 fossil species from the newer Tertiaries of Britain, and that he hoped yet to add very largely to their number.

The President then proceeded to read his Anniversary Address, in which he stated that the pressure of his official duties during the period of his presidency had prevented his keeping himself thoroughly acquainted with the recent progress of geological research, and he therefore proposed in his present address to advert rather to those questions in geology which seemed to him still to require an answer. He referred to the relations between geology and cosmogony, to the effects and causes of volcanic and earthquake action, and finally to the great questions which are still unsettled as to the origin of life and the sequence of organic beings on the face of the earth. The address was prefaced by some obituary notices of Fellows and Foreign Members and Correspondents deceased during the past year, including Mr. J. Wickham Flower, Mr. J. Garth Marshall, Prof. Agassiz, and M. de Verneuil.

The Ballot for the Council and Officers was taken, and the following were duly elected for the ensuing year:—President—John Evans, F.R.S. Vice-Presidents—Robert Etheridge, F.R.S.; R. A. C. Godwin-Austen, F.R.S.; Sir Charles Lyell, Bart., F.R.S.; Joseph Prestwich, F.R.S. Secretaries—David Forbes, F.R.S.; Rev. T. Wiltshire, M.A. Foreign Secretary—Warington W. Smyth, F.R.S. Treasurer—J. Gwyn Jeffreys, F.R.S. Council—The Duke of Argyll, K.T., F.R.S.; H. Bauerman; Prof. G. Busk, F.R.S.; J. F. Campbell; Frederic Drew; Sir P. de M. G. Egerton, Bart., F.R.S.; R. Etheridge, F.R.S.; John Evans, F.R.S.; David Forbes, F.R.S.; Capt. Douglas Galton, F.R.S.; R. A. C. Godwin-Austen, F.R.S.; J. Gwyn Jeffreys, F.R.S.; Sir Charles Lyell, Bart., F.R.S.; C. J. A. Meyer; J. Carrick Moore, F.R.S.; Joseph Prestwich, F.R.S.; Prof. A. C. Ramsay, F.R.S.; Samuel Sharp, F.S.A.; Warington W. Smyth, F.R.S.; Prof. J. Tennant, F.C.S.; W. Whitaker, B.A.; Rev. T. Wiltshire, F.L.S.; Henry Woodward, F.R.S.

Anthropological Institute, Feb. 24.—Sir Duncan Gibb, Bart., M.D., in the chair.—Mr. Biddle Lloyd, C.E., F.G.S., read a paper on the Beo hucs, a tribe of Red Indians, supposed to be extinct, which formerly inhabited Newfoundland. The author, after reviewing the various accounts related of the aborigines of the island from the time of Sebastian Cabot downwards, gave the results of the information he picked up from various sources during an exploratory cruise he made last summer round the coast of Newfoundland, respecting the strange tribe of Indians which inhabited the island up to a period which terminated about forty years ago, when, by reason of the cruelties practised on them by the English fishermen, and the warfare carried on against them by the Mic-mac Indians, they were reduced in number, and finally the few of them that were left, it is supposed, crossed over the straits of Belleisle, or at all events disappeared. Several singular circumstances in connection with the Beothucs, as they styled themselves, were noticed: namely, the curious shape of their birch-bark canoes, the fact that the dog was not domesticated by them, and their manner of hunting the Caribou by means of long lines of fencing put up to keep the herds of deer along certain tracks.—Mr. Lloyd also read notes on Indian remains found on the coast of Labrador. The Indian remains found on the coast of Labrador consisted of rudely-constructed buildings, of stone slabs, which were discovered on the sea-shore at the western entrance of the straits of Belleisle. They were described to the author as Indian graves, but there was no evidence to show that such was the use to which they had been applied. On the contrary, it seemed probable they were stone wigwams built by some Indian families for a summer residence. The author was fortunate enough to discover at L'Anse du Diable, which is a cave situated about 20 miles east of the locality where the so-called Indian graves were found, a few arrow-heads of quartzite and hyaline quartz on a sandy "barren" which stretched inland from the head of the cave. From circumstances connected with the cave, the author concluded that the locality had been chosen by some unknown tribe of Indians for the manufacture of their arrow-heads during an occupancy of some considerable time on the spot.—A paper was read by Dr. Sinclair Holden on a peculiar Neolithic implement from Antrim.

Royal Horticultural Society, Feb. 10.—Annual General Meeting.—Viscount Bury, president, in the chair.—The Report of the Council having been taken as read, it was moved by Mr. Haughton as an amendment to the motion for its adoption, and seconded by the Rev. C. P. Peach, that the meeting be adjourned to enable the opinion of the Court of Chancery to be taken as to the legal position of the Society. (The commissioners of the Annual International Exhibitions dispute the validity of the election of the Council chosen last year.) The amendment being put to the vote was lost by a majority of six, the numbers (including ladies' proxies) being, for, 225; against, 231. The report was then put and carried. The following vacancies were filled for the ensuing year:—President—Viscount Bury, K.C.M.G. Treasurer—Mr. Bonamy Dobree. Secretary—Mr. W. A. Lindsay. Members of Council (extraordinary vacancies)—Lieut.-Gen. Hon. Sir A. H. Gordon, K.C.B.; Mr. Joseph Robert Tritton; Mr. Burnley Hume; Mr. Henry Webb.

General Meeting, Feb. 18.—Henry Little in the chair.—The Rev. M. J. Berkeley commented on a plant shown by Mr. Bull, under the name of *Rapatea pandanoides*. It is a species of *Saxofridericia*. He also gave some account of Dr. Cunningham's microscopic examinations of air in Calcutta.

Scientific Committee.—A. Smee, F.R.S., in the chair.—A large number of subjects were brought before the Committee. Among the more important were—Mr. Grote: The Tea-bug of Assam, supposed by Prof. Westwood, from the figures, to belong to the Cimicideous family, Capsidæ, and nearly allied to a species which injures chrysanthemum-buds. Mr. A. Müller thought it much more likely to be some aphis, though it might be immature.—A communication was sent through Dr. Hooker on a new disease of the coffee plantations in India (Tellicherry). The leaves turn yellow, and the back is found to be covered with a rust-coloured dust. Further information was requested.—Prof. Thisselton Dyer exhibited specimens of the Balaniform gabsy gall of the oak with specimens of the Cynips which had been bred from them. These had been identified by the Rev. T. A. Marshall as *C. radicis*, Fab. He also read a note from Mr. Fenn, of Woodstock, as to the practical impossibility of making keeping wine from out-door ripened grapes without the addition of sugar—a point of interest in connection with the supposed deterioration of the English climate; also a note on the condition of an armour-plated ship which was being rapidly destroyed by dry-rot, and a photograph of the tree of the orange or Pearmain apple, with a drawing of the branch which had produced the russet sport exhibited to the Committee last November.

Entomological Society, Feb. 16.—Sir Sidney Smith Saunders, C.M.G., president, in the chair.—Mr. Weir exhibited a sample of wheat from Australia infested with a weevil, *Sitophilus oryzæ*; the cargo was so much damaged that about two tons were utterly useless. The weevil was accompanied by *Læmophlœus ferrugineus*. Some wheat from Japan was also infested with *Sitophilus granaria* and *Rhizopertha pusilla*.—Mr. Higgins exhibited a number of *Cetoniidæ* from the Philippine Islands, which had been described by Dr. Mohnike.—Mr. F. Smith read extracts from a letter from Mr. J. T. Moggridge of Mentone, on a small beetle, *Coluocera attæ*, Kraatz, found in the granaries of *Aphænogaster* (*Atta*) *structor*; and stating that *Platyarthrus* was also very common in the nests. He was much struck by the frequent occurrence of the nests of trap-door spiders in the very soil of the ants' nests; the spiders' tubes often running quite close to, and in the midst of, the galleries of the ants. As ants form a large portion of the food of trap-door spiders, this helped him to understand how it was that the spiders got a living without leaving their nests.—Some conversation took place on the ravages of the Colorado potato beetle (*Doryphora decemlineata*) in North America; a writer in the *Times* recommending the encouragement of small birds as the best security against the pest; but it was much doubted whether the small birds would

care to meddle with the insect, as it was stated that when crushed it caused blisters on the skin, and that if a wound was touched severe inflammation and painful ulcers followed.

Institution of Civil Engineers, Feb. 10.—Mr. T. E. Harrison, president, in the chair.—The paper read was on the construction of Harbour and Marine Works with artificial blocks of large size, by Mr. Bindon Blood Stoney, M.A. The author described a new method of submarine construction, with blocks of masonry or concrete far exceeding in bulk anything hitherto attempted. The blocks were built in the open air on a quay or wharf, and after from two to three months' consolidation, they were lifted by a powerful pair of shear legs, erected on an iron barge or pontoon. When afloat, the blocks were conveyed to their destination in the foundations of a quay wall, breakwater, or similar structure, where each block occupied several feet in length of the permanent work, and reached from the bottom to a little above low-water level. The superstructure was afterwards built on the top of the blocks in the usual manner by tidal work. By this method the expenses of cofferdams, pumping, staging and similar temporary works were avoided, and economy and rapidity of execution were gained, as well as massiveness of construction, so essential for works exposed to the violence of the sea.

EDINBURGH

Royal Society, Monday, March 2.—Sir Robert Christison, honorary vice-president, in the chair.—The following communications were read:—"On the Parallel Roads of Glen Roy, with a Notice of finding Fossil *Diatomaceæ* in the Deposits," by the Rev. Thomas Brown.—"On the Perception of Musical Sounds," by Dr. M'Kendrick.—"On the Establishment of the Elementary Principles of Quaternions on an Analytical Basis," by Mr. G. Plarr. Communicated by Prof. Tait.—"Preliminary Note on Spectra under exceedingly small Pressures," by Prof. Tait and Mr. J. Dewar.—"Laboratory Notes," by Prof. Tait (1) On Atmospheric Electricity; (2) On the Thermoelectric Position of Sodium.

DUBLIN

Royal Irish Academy, Feb. 9.—Rev. J. H. Jellett, president, in the chair.—W. H. Baily, F.L.S., read a preliminary report on the plant-fossils of the Kiltorkan district. In this preliminary report Mr. Baily stated that the most frequent plant met with is *Palæopteris hibernica*, first noticed by the late Prof. E. Forbes, under the provisional name of Cyclopteris, afterwards referred to Adiantites by A. Brogniart, and now placed by Schimper in his genus Palæopteris, differing as it does from the former genus in the arrangement of its leaflets and from the latter in its mode of fructification. Some of the fronds met with were nearly five feet long and three wide. Two new species were described as *Sphenopteris hookeri* and *S. humphresianum*, both of which were comparatively rare.—A fine example of the stem of *Sagenaria baileyana* of Schimper was met with, the total length of which was 20 ft. 4 in., and at its lowest portion it was 6 in. in diameter; it branched at about 15 ft. from the base; and the upper portion of these branches corresponds with *Cyclostigma minuta* of Haughton. Cone-like bodies, somewhat resembling Lepidostrobus of the coal were met with. They are composed of elongated scales, terminating in long linear processes showing large and very distinct sporules.—These presumably belong to the Sagenaria but have never yet been found attached.—The report was referred to Council for publication.—Mr. G. Kinahan, of the Geological Survey, believed the report was a most valuable one, and that the researches of Mr. Baily had proved that many of Mr. Carruther's species were but portions of the same plant.—Prof. M'Nab read a report on some researches into the physiology of plants. These experiments were first a series to determine the amount of water transpired by leaves, and secondly the ascent of water in the stem. The plants selected for both series of experiments were the cherry-laurel, the common privet, and the common elm. It would be impossible to condense the large series of experiments made by the author. One series, to determine the amount of water transpired by leaves, made on August 7, 1873, showed that, with very nearly the same exposure and under the same conditions, the cherry-laurel lost, of water, 51·81 per cent. of the weight of the branch employed; the privet, 26·78; the elm, 65·61. Very many experiments were made to determine the actual rate at which fluid ascends in the stem. In Sach's experiment on this subject he fixed the rate to be 9 in. per hour. In Dr. M'Nab's first experiments he obtained a rate of 24 in. per hour. The present series of experiments were made on the same species of plants mentioned above. In the privet the rate was 6 in. per hour; in the elm the rate was 15·6 in. per hour. But in both plants the leaves and stem soon became placid, and the experiments were not completely satisfactory. In the cherry-laurel the rate in one experiment was 24 in. per hour; in a second, 13·2 in. per hour; and in a third, 18·6 in. per hour. The author also recorded a large series of experiments: 1. As to the rapidity of the ascent of fluid in stems when in (*a*) sun, (*b*) diffused daylight, and (*c*) darkness. 2. Rapidity of ascent in branches cut off in the dark. 3. Rapidity of ascent in branches with the cortical tissue removed. 4. Rapidity of ascent in stems deprived of their leaves. 5. Rapidity of absorption of lithium when applied at apex of the branch; and 6. Rapidity of ascent when fluid was taken up under pressure of mercury, intended to represent the root pressure of the plant.—This report was also referred to Council for publication.

VIENNA

Geological Institute, December 3, 1873.—One of the most obscure questions in the geology of the Austrian empire has been the geological position of the Vienna and Carpathian sandstones which form a broad continuous zone on the northern flank of the Austrian Alps, and by far a broader one still on the northern and eastern flank of the Carpathians in Moravia, Silesia, Hungary, Galizia and Transylvania. Only in Silesia, by the investigations of the late Hohenegger, and in Northern Hungary, by those of M. C. Paul, a more satisfactory knowledge has been obtained on this subject. They agree that in both regions the Carpathian sandstones may be divided into several easily distinguishable groups which belong partly to the older tertiary, and partly to the cretaceous formations. Two very valuable memoirs on this subject were read; the first from M. F. Herbich, on the Carpathians in Eastern Transylvania, between the Gyimes and the Tomos Pass. The lowest member of the Carpathian sandstones is formed here by white or yellowish sandstones, which, higher up, pass into coarse conglomerates and belong to the middle neocomian formation; they are covered by a large series of dark-grey sandstones which contain characteristic fossils, and belong to the upper neocomian. The next member, developed near Zaizon, is a grey limestone with Caprotina Lonsdali, identical with the well-known Caprotina limestone of the Alps, and belonging also to the upper neocomian. Above the neocomian strata follow again different sandstones, which M. Herbich thinks to be identical with the Godula sandstones of Hohenegger, and therefore to belong to the Gault. The second memoir, by M. Ch. Paul, treats of the Carpathian sandstones in the eastern Bukowina. They are divided in five different stages, viz., (1) Lower Teschen slates; (2) Neocomian Aptychus limestones; (3) Ropianka beds; which were formerly thought by the author to belong the Eocene series, whilst now he considers them as probably Cretaceans. They are of very great importance, because they contain in Galicia and Bakowina, as well as in Hungary, exclusively the sources of petroleum. 4. Menilith schists, with nests of fossil fishes, which are generally thought to belong to the middle oligocene formation. 5. Magara sandstone, probably upper oligocene.—Dr. Neumayer on the character and the distribution of some Neocomian cephalopods. The author, referring to a former memoir, ("Jahrb. d. k. k. geol. Reichsaunstalt," 1871, p. 521), states that the European jurassic deposits form three different provinces, the Mediterranean, the middle European, and the Russian province. By very interesting observations on the faunas of these provinces, as well as on that of the neocomian period, he establishes some facts relating to the physical geography of the mesozoic period. First he states, that at the end of the jurassic time, the middle parts of Europe were laid dry, and whilst therefore the marine life in the middle European province ceased, it continued, and was differently developed in the Mediterranean (deposits of Stramberg, of Berrias, &c.) and in the Russian province. Afterwards, about the time of the Valenginien, the middle part of Europe was again submerged and now peopled partly from the northern and partly from the southern seas; that the immigration went really partly from the north, is proved by the very curious and close affinities between some of the middle European neocomian cephalopods and those of the upper jurassic strata of Russia.

Academy of Natural Sciences, Dec. 11, 1873.—M. Hoernes described the geological features of the island of Samothrace, from observations made in the spring of 1873.—Prof. Knoll presented a paper on the reflex effects produced

on respiration, by introducing some volatile substances into the air passages under the larynx. When chloroform is inhaled through a tracheal canula (the mucous membrane of the nose being guarded against its action), there is acceleration and shallowing (*Verflachung*) of the respiratory movements, with low position of the diaphragm, and, sometimes, entire stoppage in the position of inspiration. Ether, benzine, and oil of mustard have a similar, though less, effect. Section of the vagi at the neck shows that these changes depend on reflex action of the vagi. The vapour of a strong solution of ammonia produces great change in the respiration, often lasting several minutes, and varying between a retarding and deepening effect, with long stoppage in position of expiration, and retardation and shallowing in position of inspiration. This also is due to reflex action through the vagi. Inhalation of pure carbonic acid through the tracheal canula produces, both when the vagi are cut and uncut, first, a moderate acceleration, then a considerable retardation of the respiratory movements. No phenomenon occurs which can be explained by a direct stimulation of the vagi by the Co_2.—Dr. Fitzinger communicated a paper on the species of the family of deers (*Cervi*) according to their natural relations. He enumerates twenty different species, four of which he has himself introduced, viz., *Strongyloceros*, *Elaphoceros*, *Doryceros*, and *Nanelaphus*. To Wagner's species *Macrotis* and *Furcifer*, he gives the names *Otelaphus* and *Creagrocerus*, the two former names having had a previous application in zoology. Dr. Schenck presented a note on the eggs of *Raja quadrimaculata* within the oviduct; describing the structure of the shell, and the development of the embryo.—Drs. Nowak and Kratschmer made a communication on phosphoric acid as a re-agent with alkaloids. They find that it gives, with several alkaloids, peculiar colour-reactions, in some of which characteristic reactions of smell are developed. In both respects it presents some advantages over the similarly-acting sulphuric acid. It is specially preferable to this in determination of atropia, for reasons which the authors give.

PHILADELPHIA

Academy of Natural Sciences, Oct. 7, 1873.—Dr. Ruschenberger, president, in the chair.—"Law of Seed Germination in Swamp Plants." Mr. Thomas Meehan said that it was an error to suppose that Nature placed trees in places the best suited to their growth. Almost all of our swamp trees grew much better when they could get into dryer places, if in ordinary good land. He referred among others to *Magnolia glauca*, *Acer rubrum*, *Celtis occidentalis*, *Ilex opaca*, *Cupressus chamæcyparis*, *Cephalanthus occidentalis*, *Salix babylonica*, especially as, within his own repeated observations, growing better out of swamps than in them. Why it was that they grew in swamps was no enigma to those in the habit of raising forest trees from seed. It was found that seeds of these trees would only germinate in damp places, and, of course, in a state of nature the tree had to remain in the place where the seed germinated. He thought the principle taught that plants required water to grow well was true only in so far as a humid condition of the soil was concerned. Plants as a general thing, though they were of the class known especially as water plants, preferred to grow out of the water, except in those which grew almost entirely beneath the surface. As was well known, the *Taxodium distichum* in the southern swamps sent up "knees" from various points as the roots extended, often as large as old-fashioned bee-hives, and several feet above the surface.

Oct. 21.—Dr. Ruschenberger, president, in the chair.—"Stibiaferrite, a new Mineral from Santa Clara County, California," by E. Goldsmith.

Oct. 28.—Dr. Ruschenberger, president, in the chair.—The following paper was presented for publication:—"Descriptions of Mexican Ichneumonidæ," by C. T. Cresson.

Nov. 18.—Mr. Vaux, vice-president, in the chair.—The following papers were presented for publication:—"On the Homologies and origin of the Types of Molar Teeth in Mammalia Educabilia," by E. D. Cope; "Contribution to the Ichthyology of Alaska," by E. D. Cope. Prof. Cope remarked that he had observed in the Rocky Mountain region circles of stones arranged by human hands, in countries not now inhabited by the Indians. One of these is in South-western Wyoming near South Bitter Creek, inside the horseshoe of the Mammoth Buttes. The locality is a very barren one, and could hardly be regarded as a camping-ground. The circle consists of three uninterrupted concentric rings close together, the hole having a diameter of about 15 ft. The stones are of moderate size, composed of a dark silex, and evidently derived from the drift material brought down from the Uinta Mountains, which is found on the summits of the bad-land mesas. Five or six miles from this place was found a flint factory with numerous implements and cores. Two other circles were observed, in Colorado, about a hundred miles east of Long's Peak, and about five miles from a spring in a well-grassed country. The locality is unsuitable for a camp, in consequence of the remoteness of wood and water. The country is not inhabited by Indians, the nearest, a temporary camp, for travelling Cheyennes, Sioux, &c., being forty miles distant.

Nov. 25.—Dr. Ruschenberger, president, in the chair.—The following paper was presented for publication:—"Description of Seven New Species of Unionidæ of the United States," by Isaac Lea. The committees to which were referred the following papers:—"On the Homologies and Origin of the Types of Molar Teeth in Mammalia Educabilia," by Edward D. Cope; and "Contributions to the Ichthyology of Alaska," by Edward D. Cope," reported in favour of their publication in the *Journal*.—Disposition of the *Flexor perforans*, *Flexor longus hallucis*, and *Flexor accessorius* in *Paradoxurus musanga* Gray, by Dr. H. C. Chopman.

PARIS

Academy of Sciences, Feb. 23.—M. Bertrand in the chair. The following communications were made:—On the undulatory movement of a train of wagons due to a shock, by M. H. Resal.—On the acid waters which rise in the Cordilleras, by M. Boussingault.—Determination of vapour densities, by H. Sainte-Claire Deville. The author criticised the apparatus for the determination of vapour densities, recently devised by M. Croullebois.—M. Dumas communicated a note on a process invented by Dulong for taking vapour densities.—Observations concerning the last communication by M. Clausius, on the equation $\int \frac{dQ}{T} = 0$, by M. A. Ledieu.—M. Milne-Edwards gave news of l'Abbé A. David, now travelling in Western China, and presented, on the part of this naturalist, a note containing descriptions of several new birds.—Memoir on the swim-bladder from the point of view of station (*station*) and locomotion, by M. A. Moreau. The author described some experiments made upon a perch (*Perca fluvialis*).—Organogenesis compared with Androgenesis in its relations to natural affinities (*Class Œnotherinæ*), by M. A. Chatin.—On a new mode of ramification observed in plants of the family of the Umbelliferæ, by M. D. Clos.—Observations relative to a recent memoir by M. Helmholtz upon "Aërial Navigation," by M. W. de Fonvielle. On the lines which are doubly tangential, to the "*surface lieu*" of the centres of curvatures of a surface of the second order, by M. Laguerre.—On the permanent magnetism of steel, by M. E. Bouty.—Note on the distribution and determination of thallium, by Mr. T. L. Phipson.—On the presence of metallic silver in gallena, by the same author.—Anatomical researches on rickets of the vertebral column," by M. Ch. Robin.—Geological sketch of the Isle of Tros, by M. H. Gorceix.—On a new apparatus for registering the direction of clouds, by M. H. de Parville.—On three new human skeletons discovered in the caves of Menton, and on the disappearance of chipped flints and their replacement by sandstone and limestone instruments, by M. E. Rivière.—On pine-culture in Central France, by M. de Béhague.

CONTENTS

THURSDAY, MARCH 12, 1874

THE LINNEAN SOCIETY

ON Thursday last the Fellows of the Linnean Society met together in a general meeting, which had been specially convened to consider the disputes which have almost paralysed its work for the past two months. One painful episode which arose out of these disputes has already been alluded to in these columns. This alone gave importance to matters which otherwise it would have been difficult to discuss with patience. But so serious a crisis as the resignation of a president so distinguished as Mr. Bentham brought together a larger meeting of the Fellows than had probably ever assembled together before in the history of the Society, and produced the very decided feeling that at least the prospect of a settlement must be reached before the meeting dispersed.

The result was, on the whole, a satisfactory one. After a debate which lasted for about two hours, and in which a considerable number of Fellows took part, a motion proposed by Major-General Strachey was finally carried with only three dissentients, to the effect that the Council possessed the confidence of the Fellows, and that the question of the disputed bye-laws should be referred to some authoritative legal adjudicator, whose decision should be regarded as final.

Those who have had no opportunity of taking any part in the proceedings will naturally wonder what can have been the nature of the portentous questions which have so violently disturbed so grave and staid a body as the Linnean Society. So far as we can arrive at a clear comprehension of the facts, they may be stated as follows :—

At the commencement of the present year the charter and bye-laws were out of print, and the Council having determined to reprint them, before doing so made and submitted to the Fellows a number of amendments in them which appeared to be advisable. It is necessary to explain that, by the constitution of the Society the Council alone has the power to legislate, and the general body of Fellows is only able to reject or ratify what the Council has done. At the meeting on January 15, when the amendments in due course came before the Fellows, the President was requested to put them to the vote *seriatim*, and not *en masse*. This was *primâ facie* a reasonable request, and might, perhaps, have been acceded to without any great inconvenience. The President, however, ruled against it, and his ruling may be defended on two grounds. In the first place the custom of the Society on other occasions appears to have been in accordance with it, and as a general principle it seems obvious that it would be inconvenient for the Fellows to modify in detail a scheme which the Council had presented to them as a whole. In the second place, although the charter is a most difficult instrument for a layman to interpret, it is held by those who ought to be able to construe it, to require that the Council's propositions should be accepted or rejected in their entirety and without modification. The amendments were accordingly put to the meeting *en masse*, and were carried by the necessary majority of two-thirds. The minority declared themselves much aggrieved by the course that had been taken. It is not easy, however, to appreciate their objection ; for it is clear that to put all the amendments *en masse* cannot facilitate their acceptance, but that, on the contrary, it brings to bear collectively upon the whole scheme all the objections which might be raised separately to different parts of it.

At the meeting in which the amendments were carried, only one of them was actually objected to. The effect of this amendment was to enable the Council to pay a Fellow to assist in editing the publications. The sum proposed was not large, and it seems very desirable that the work should be paid for, and not voluntary. It is quite obvious that in the former case the secretaries would have no scruple in criticising, if necessary, what was done, which might easily seem an ungracious proceeding in the case of unpaid labour.

Subsequently, however, to the meeting, the minority discovered that another amendment, removing the appointment of the Librarian from the general suffrages of the Fellows to the Council, was repugnant to the provisions of the charter. A competent legal authority has declared that this is not the case ; nevertheless, certain of the Fellows hold a contrary opinion, and regard the change as a derogation from their privileges.

We have already referred to what took place on February 5. Mr. Carruthers, who took the lead in the opposition, proposed to discuss the legality of the amendments, and attempted to raise this question upon the confirmation of the minutes of the meeting at which they had been carried. He and his supporters being in a majority in a very thinly-attended meeting refused to acquiesce in the ruling of the President against the regularity of this proceeding; the meeting broke up in confusion, and Mr. Bentham resigned the chair which he has occupied so long to the great advantage of the Society. The difficulties of the Society began like a slight and neglected illness which terminates fatally : before the general body of Fellows had time to even realise the nature of the dispute it had culminated in an event which it will never be possible to look back upon except with the strongest regret. It was, however, a matter for satisfaction that the Fellows assembled last Thursday were anxious to efface this from Mr. Bentham's recollection ; and Mr. Carruthers, whose action was the immediate cause which led to the President's resignation, spoke with befitting dignity of the regard he felt for Mr. Bentham's services to the Society and to Science generally, and of his own extreme regret that the course he had considered himself compelled to take had led to such an untoward result.

As to the points apparently in dispute it is difficult to estimate seriously the position of the dissidents from the Council's action. It is objected that the person employed as sub-editor ought not to be a Fellow, or ought on accepting the position *ipso facto* to cease to be one. But where, it may be asked, can the Society expect to find, except in its own ranks, anyone competent for the work? and why should there be any more scruple about employing a Fellow for such a purpose than there is in employing Fellows as printers and engravers?

As to the election of a Librarian, what arrangement could be more objectionable than for the Society at large to elect to an office of this kind? How could testimonials

be properly weighed by the members generally, or the fitness of candidates in any way tested? And when it is argued that the clerk and housekeeper, as well as the Librarian, ought to be appointed by the Society also, and not by the Council, the acme of absurdity in the matter seems to have been reached.

It is quite evident, from what has been said, that the less a learned Society indulges in legislation the better. What must be called the "opposition" were anxious, at the meeting on Thursday last, for a further revision of the whole laws of the Society; fortunately, however, the common sense of the Fellows was against them. Sir John Lubbock pointed out, at the conclusion of the debate, that none of the speakers had made out even a *primâ facie* case for further change. It may be hoped, therefore, that when the technical question of the legality of the amendments has been disposed of, the Society will enjoy undisturbed peace and quietness.

One practical suggestion seems to educe itself from what has been said. The only way to settle matters of dispute of this kind is to have an authoritative arbitrator. If we ever get a minister to take charge of our scientific institutions, a legal assessor might be conveniently attached to his staff to act in lieu of a Visitor to the learned Societies which now possess a quasi-official status from being housed at the public expense. If the points which the dissentients raised in the present case could have been authoritatively and impartially settled off-hand, there would have been no need for an important scientific Society to have wasted a considerable portion of its session over matters in themselves of the slenderest possible consequence, and absolutely without importance in a scientific sense.

THE MOON

The Moon Considered as a Planet, a World, and a Satellite. By James Nasmyth, C.E., and James Carpenter, F.R.A.S. With 24 illustrative plates of lunar objects, phenomena, and scenery, and numerous woodcuts. (London: Murray, 1874.)

THE illustrations to this book are so admirable, so far beyond those one generally gets of any celestial phenomenon, that one is tempted to refer to them first of all. No more truthful or striking representations of natural objects than those here presented have ever been laid before his readers by any student of Science; and I may add that, rarely if ever, have equal pains been taken to insure such truthfulness. Mr. Nasmyth, not content with the drawings he has been accumulating for many years, has first translated them into *models*, which, when placed with a strong light shining obliquely upon them, should reproduce the ever-changing lunar effects of light and shadow. Having obtained models which bore this test, he has photographed them with the light falling, now on one side, and now on the other, to represent the sunrise and sunset appearances on our satellite, as observed in the telescope. The result is perfect; far more perfect than any enlargement of photographs could possibly have been, because, by every such enlargement, a softness is brought about, whereas, the more powerful the telescope employed and the more perfect the atmospheric conditions, the more does the unevenness and sharpness of every lunar detail come out.

But, though I have given the first place to a general reference to the illustrations, I by no means intend thereby to imply that the text is of secondary importance. In fact, the more carefully the text is read, the more obvious does it become that Mr. Nasmyth has used his drawings as a means to an end, and that he and Mr. Carpenter between them have produced a work which is not only a very beautiful and a very readable one, but one of some importance. From this point of view it is to be regretted that the book had not been published a month or two later, as then the authors might further have illustrated their subject by a reference to Mr. Mallet's most important paper on volcanic energy, which has just appeared in the "Philosophical Transactions"—a paper which supports the authors' views in many important particulars, and though it clashes with others, if we are not mistaken, a discussion of the question from the two points of view presented will ultimately enable us to carry our conclusions further than they have gone hitherto.

Again, it is not a little curious that another communication presented to the Royal Society not long ago, and

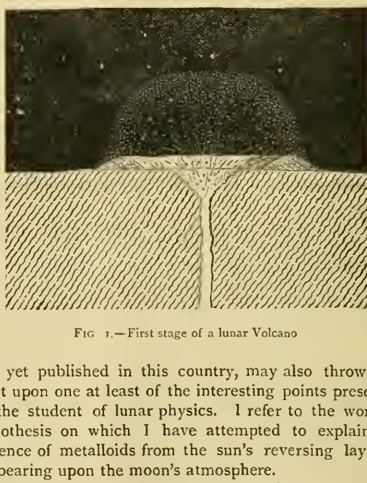

FIG. 1.—First stage of a lunar Volcano

not yet published in this country, may also throw new light upon one at least of the interesting points presented to the student of lunar physics. I refer to the working hypothesis on which I have attempted to explain the absence of metalloids from the sun's reversing layer in its bearing upon the moon's atmosphere.

Before, however, more detailed reference to these points, it is as well to state briefly, for those less conversant with lunar matters, the principal points in which Selenology differs from Geology, or rather the principal effects which have been produced on the moon in past time which differ from the effects which have been produced on our planet in past time.

First among these is undoubtedly the evidence of volcanic action on a scale far surpassing anything that we have an idea of here. Witness craters 74 miles in diameter, and if the walled plains are accepted as craters, then diameters of craters reaching 300 miles, the volcanic energy not being scattered here and there, but making up the entire surface over large areas.

Next, after the tremendous evidence of vulcanicity afforded by the craters and walled plains, come the bright streaks which have ever been a puzzle to observers. These are seen under various illuminations to radiate from several craters for hundreds of miles. Here I will quote from the book, p. 133:—

"There are several prominent examples of these bright streak systems upon the visible hemisphere of the moon; the focal craters of the most conspicuous are Tycho, Copernicus, Kepler, Aristarchus, Menelaus, and Proclus. Generally, these focal craters have ramparts and interiors distinguished by the same peculiar bright or highly reflective material which shows itself with such remarkable brilliance, especially at full moon; under other conditions of illumination they are not so strikingly visible. At or nearly full moon, the streaks are seen to traverse over plains, mountains, craters, and all asperities; holding their way totally disregardful of every object that happens to lie in their course. The most remarkable bright streak system is that diverging from the great crater Tycho. The streaks that can be easily individualised in this group number more than one hundred, while the courses of some of them may be

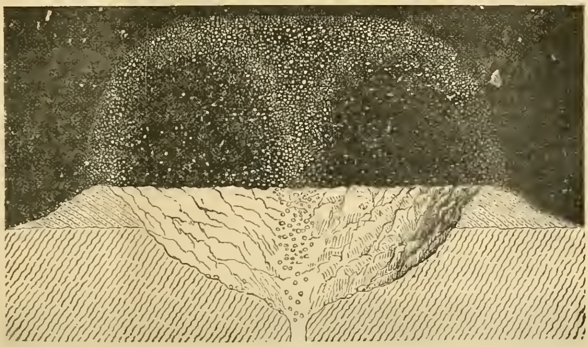

FIG. 2.—Second stage. The crater increases its diameter

traced through upwards of six hundred miles from their centre of divergence. Those around Copernicus, although less remarkable in regard to their extent than those diverging from Tycho, are nevertheless in many respects well deserving of careful examination; they are so numerous as utterly to defy attempts to count them, while their intricate reticulation renders any endeavour to delineate their arrangement equally hopeless."

Quite different from these radiating streaks are very definite "cracks," some of which are easily seen with moderate telescopic powers. There are, however, a very large number recorded, some of which are excessively delicate objects.

Last among exceptional phenomena to be recorded is the circumstance that our satellite has no atmosphere to speak of: no clouds, no fogs have ever been seen on the moon as on Mars, while no effects have been produced

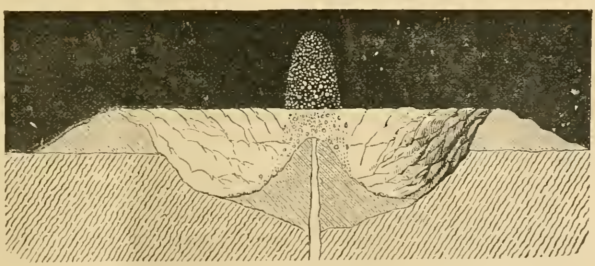

FIG. 3.—Third stage. The central cone is formed by a reduced action

at occultations of stars and planets by the moon such as should be produced did an atmosphere in any way comparable to our own exist on our satellite.

Although the most important part of the text consists of an attempted explanation of all but the atmospheric phenomena, much of it deals, and in a very admirable way, with lunar topography, a perusal of which will be desirable before the discussion is taken up, in the case, at all events, of those unfamiliar with the moon's surface. The consideration of the various questions involved is preceded by chapters on the cosmical origin of our system and the generation of heat, the result of which was that at one time the moon was an incandescent sphere with a cooling crust, and even then if I understand the authors, there was no lunar atmosphere (p. 17), for they give an answer, or think they do, in this sense to the question

"How can a volcanic theory of the lunar phenomena be upheld consistently with the condition that it possesses no atmosphere to support Fire?"

In the chapter on the cooling of the crust (Chap. III.), special attention is directed to observations tending to show that cast-iron and even slag and Vesuvian lava expand on cooling. This will be new to physicists:—

"The broad general principle of the phenomenon here referred to is this: That fusible substances are (with few exceptions) specifically heavier while in their molten condition than in the solidified state, or in other words, that molten matter occupies less space, weight for weight, than the same matter after it has passed from the melted to the solid condition. It follows as an obvious corollary that such substances contract in bulk in fusing or melting, and expand in becoming solid. It is this expansion upon solidification that now concerns us.

"Water, as is well known, increases in density as it cools, till it reaches the temperature of 39° F., after which, upon a further decrease of temperature, its density begins to decrease, or in other words, its bulk expands, and hence the well-known fact of ice floating in water, and the inconvenient fact of water-pipes bursting in a frost. This action in water is of the utmost importance in the grand economy of nature, and it has been accepted as a marvellous exception to the general law of substances increasing in density (or shrinking) as they decrease in temperature. Water is, however, by no means the exceptional substance that it has been so generally considered. It is a fact perfectly familiar to iron-founders, that when a mass of solid cast-iron is dropped into a pot of molten iron of identical quality, the solid is found to float persistently upon the molten metals—so persistently that when it is intentionally thrust to the bottom of the pot, it rises again the moment the submerging agency is withdrawn" (p. 20).

There will be many for whom this part of the work will possess great interest, but I take it few will accept the startling conclusions drawn from the asserted expansion.

"This expansion of volume which accompanies the solidification of molten matter furnishes a key to the solution of the enigma of volcanic action; and that such theories as depend upon the agency of gases, vapours, or water are at all events untenable with regard to the moon, where no gases, vapour, or water appear to exist" (p. 27).

I will return to this point presently, but meantime let us follow the contracting globe. Messrs. Nasmyth and Carpenter quite accept tangential pressure as being the only true cause of elevation, and its effect is very well put:

"When the molten sub-stratum had burst its confines, ejected its superfluous matter, and produced the resulting volcanic features, it would, after final solidification, resume the normal process of contraction upon cooling, and so retreat or shrink away from the external shell. Let us now consider what would be the result of this. Evidently the external shell or crust would become relatively too large

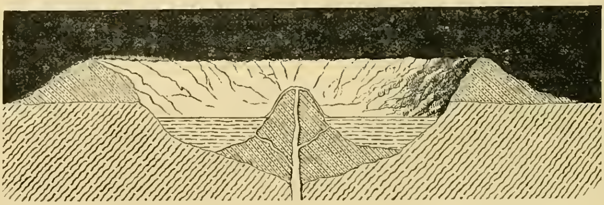

FIG. 4.—Fourth stage. The old crater is nearly filled with lava, leaving the cone visible in the centre

to remain at all points in close contact with the subjacent matter. The consequence of too large a solid shell having to accommodate itself to a shrunken body underneath, is that the skin, so to term the outer stratum of solid matter, becomes shrivelled up into alternate ridges and depressions or wrinkles" (p. 28).

The preceding extracts will give an idea of the authors' view of the general phenomena which accompanied the cooling of the crust. We have no atmosphere, the crust as it cools expands and cracks, and through these cracks the interior liquid is ejected, and finally tangential pressure does the rest.

Now leaving the question of the atmosphere for a time, let us compare this with Mr. Mallet's reasoning. As a planet cools, the crust thickens, and the nucleus contracts; the crust must follow the nucleus, hence tangential pressure and its concomitants, elevation where possible, where not possible then tremendous interior motions, which motions are converted into heat, which heat + water produces volcanic activity. Further, the smaller a globe is, the more rapidly will it cool, and the more marked will the phenomena which accompany cooling be. Hence Mr. Mallet's hypothesis is competent to explain all the extreme development of volcanic activity on the moon by exactly similar causes which we know to have gone on here.

Now as I have said, Mr. Mallet wants water for his volcanoes, both here and on the moon, but Messrs. Nasmyth and Carpenter will not even allow that an atmosphere, still less water, has ever existed there. Now here I unhesitatingly range myself on the side of Mr. Mallet. I believe in an absolute uniformity throughout all Nature in such matters. I do not mean uniformity of matter, so far as chemical materials go, but of manner.

Now what is an atmosphere? or to put the question more specifically, what is our atmosphere? Is it not a residue? We have free oxygen in the atmosphere at the present time; had we not very much more before the various metals which now exist in combination with that metalloid existed in their pure state? Now how has combination been brought about? By exposing the metals to the atmosphere and its contained oxygen. Now suppose the machinery, the function of which in past time has been to bring these metals to the surface, had been a thousand times more powerful, would there be as much oxygen in the air now as there is? A child can answer this question, and it is one of several which might be asked all tending to show that it is as unnecessary as it is unphilosophical to suppose that there never was a lunar atmosphere, because there is only a tenuous one at the best now. I shall not

follow this subject out further now because it is part of a larger one, which deals with the atmospheres and densities of all the bodies of our system, and to discuss it at length would lead me too far from the present subject; suffice it to say that the enormous atmospheres of Saturn and Jupiter and the absence of a lunar atmosphere result from one single cause, that cause being if I mistake not the chemical constitution of the exterior parts of the solar nebula as each planet was thrown off, and the subsequent action on each globe.

To come to details. Whether the walled plains are really due to volcanic action or not, our authors offer no opinion beyond referring to the hypothesis of Prof. Dana, as being the most rational. Dana suggested that, as at Kilauea, the lava was simply boiling, and gradually extending its boundaries from a centre, so that at last, if the heat continued, a quasi-crater might be formed of any extent. That the smaller craters are true craters Messrs. Nasmyth and Carpenter take great pains to show, and their evidence is of the closest and most satisfactory kind. The woodcuts which we produce will show how the central cones, which *are scarcely ever absent in the craters we are now discussing*, have originated on the theory advanced; at the same time it is shown how, on this idea, even when the central cone is absent or the crater is filled to the brim, as in the case of Wargentin, one of the most curious of lunar objects, the effects observed may be explained.

Mr. Nasmyth long ago illustrated the bright streaks on the moon by the experiment which he here details, and a very striking one it is. He took a glass globe, filled it with water, and having hermetically sealed it, plunged it into warm water, "the enclosed water expanding at a greater rate than the glass, exerts a disruptive force on the interior surface of the latter, the consequence being that at the point of least resistance the globe is rent by a large number of cracks diverging in every direction from the focus of disruption."

From the photograph, it is clear that the result is strikingly similar to the rays which have Tycho for a focus, and on the strength of this similarity the authors claim this as another effect of expansion due to cooling. I so, however, the experiment with the glass globe is not in point. But however the cracks were produced, they imagine that thus having them travelling along for hundreds of miles irrespective of surface inequality, there was an up-flow of molten matter which spread out on both sides and turned the narrow crack into a broad streak.

I trust I have said enough about this book to induce all interested in physical problems to peruse it for themselves; it is altogether an admirable production, and if space permitted each picture even would merit a special paragraph.

J. NORMAN LOCKYER

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Natural Selection and Dysteleology

IN his reply to a criticism which appeared in NATURE, Prof. Struthers alluded to a question of considerable interest to evolutionists, viz., whether or not the presence of useless organs "proves too much for the argument." * The difficulty is one often met with, and has been well stated by Prof. Huxley, thus:—"Prof. Haeckel has invented a new and convenient name, 'Dysteleology,' for the study of the 'purposelessnesses' which are observable in living organisms—such as the multitudinous cases of rudimentary and apparently useless structures. I confess, however, that it has often appeared to me that the facts of dysteleology cut two ways. If we assume, as evolutionists in general do, that useless organs atrophy, such cases as the existence of lateral rudiments of toes, in the foot of a horse, place us in a dilemma. For, either these rudiments are of no use to the animal—in which case, considering that the horse has existed in its present form since the pliocene epoch, they surely ought to have disappeared—or they are of some use to the animal, in which case they are of no use as arguments against teleology," &c.†

Now it appears to me (as I think it must to all upon adequate consideration), that the dilemma thus presented is only apparent; its first-mentioned horn having no existence. In other words, we can never in any single case be sure that any length of time would have been sufficient to enable natural selection totally to obliterate a useless organ.

Mr. Darwin, in the "Origin" and in the "Variation," has mentioned three causes which operate towards the removal of useless structures. These causes are Selection, Disuse, and Economy of Growth. Recently he has suggested a fourth cause, which may be epitomised as the dwarfing influence of impoverished conditions, progressively reducing the average size of the useless structure, by means of free intercrossing.‡ I shall endeavour to show that these causes are not sufficient to obtain the complete extinction of rudimentary parts in all cases.

Selection may be considered as applying only to those rare instances in which changed conditions of life may be supposed to have rendered a previously useful organ injurious; for so far as selection operates in obliterating a merely useless organ, it will be more convenient, for the sake of brevity, to identify it with the Economy of Growth.§ Since, however, it is obvious that an injurious organ must pass through the merely useless stage before it becomes wholly suppressed, we may dismiss this cause without further comment.

Disuse and Economy of Growth are so much entangled in their operation, that it is hopeless to find examples illustrating their separate action. In so far, therefore, as we choose to disentangle them, we must discuss the question in the abstract.

Disuse may be left out of the question, so far as its influence is due to the principle of inheritance at corresponding periods of life; for, as Mr. Darwin tersely observes, "as most organs could be of no use at an early embryonic period, they would not be affected by disuse; consequently they would be preserved at this stage of growth, and would remain as rudiments." ‖ It may,

* NATURE, vol. ix p. 83.

† "Critiques and Addresses," pp. 307–8.

‡ NATURE, vol. viii. pp. 432 and 505.

§ I think, also, that if the Economy of Growth is really a principle independent of the "more general principle," viz., the *direct* influence of "natural selection in continually trying to economise every part of the organisation" (Compare "Origin," 1873, pp. 117–18), it may yet, without any great stretch of inference, be considered as due to the *indirect* influence of natural selection. For, the survival of the fittest demands that each individual shall utilise its stock of nutriment to the best advantage; and, this demand being continued through many generations, it does not seem in itself improbable, that it should thus at last secure to all the members of the surviving species an inherited tendency so to economise their nutritive power when fresh occasion requires—an advantageous innate *temperament* distinct from the external *eliminative* agency of Natural Selection. Only in some such way can we account for the facts of acclimatisation, in those cases where the adaptive changes take place immediately after the transportation of the organism: also for an analogous class of facts, such as that of the shells in the same species of Mollusca, differing in their thickness upon the weather and the lee sides of the Plymouth breakwater.

‖ "Variation," vol ii. p. 317. I may mention, also in passing, that it seems to me not unopen to question whether disuse is the *principal* cause even of reduction There is no doubt that disuse causes more or less of atrophy in the individual, and from this fact it is argued, that the principle of inheritance at corresponding periods of life must entail the continued reduction of a disused part in the species. Now the only effect of the principle relied on is that of prolonging, as it were, the life of the disused part over many generations—thus affording it an indefinite time to succumb to the conditions which reduced it in the life of the individual. But it is necessary for the validity of the inference that it would so succumb, to show that these conditions are the efficient causes of this reducing process in the one case, as they prove themselves to be in the other. Suppose, for instance, that failure of nutrition is the principal cause of atrophy under disuse, does it follow when such failure has done, to all appearance, its utmost during the life of the individual (as we see in disease), that it could do any more were that life indefinitely prolonged? Of course in the case of short-lived animals, where the dwarfing influences may not have time to exhaust themselves in a single generation, the principle of inheritance at corresponding ages may be drawn

however, be objected that the doctrine which Mr. Darwin elsewhere inculcates,* and deems sufficient to account for the total suppression of rudimentary organs, viz., inheritance at earlier periods of life, is fatal to dysteleology as a prop to evolution—at least in the case of long-lived species. And so it would be, were not this principle of so shadowy an application that, while it is perfectly legitimate to point to it as a possible cause of total suppression in some cases, it would be simply absurd to argue that such must be its effect in all.

We next come to the Economy of Growth. Suppose an organ to become suddenly useless, this principle would at first cause its rapid reduction. In proportion, however, as its presence ceases to be injurious, the arresting process becomes slower and slower, until a point is reached at which it is presumably *nil*. That such a point of rest must somewhere be attained seems evident, if we consider that the smaller the diminishing organ becomes the less is it subject to the influence of the Economy of Growth. In other words, when the organ undergoing reduction becomes so minute relatively to the size of the animal (or, more correctly, to the available store of nutrition), that the supply of nourishment it requires is no longer perceived by the organism at large, it then remains permanently of that size. "The economy of growth will not account for the complete or almost complete obliteration of, for instance, a minute papilla of cellular tissue representing a pistil, or of a microscopically minute nodule of bone representing a tooth;"† and, the whole principle being one of relation, it is a question, for instance, whether the rudimentary digits of a horse consume a greater relative amount of nutrition than does the "minute papilla." Besides, without entering into details, I think there is very good reason to believe that the Economy of Growth is unable to reduce an organ which was originally large, to the same absolute size as it can an organ which was originally small. From all this it follows, that if the struggle for existence were in any case so keen as to afford Selection (*i.e.*, Economy) the opportunity of totally obliterating every rudimentary organ, it seems probable that the species itself would require to become extinct.

Turning now to the last of the causes propounded by Mr. Darwin, there can be no doubt that it is (theoretically) sufficient to procure total obliteration. Forasmuch, however, as we can never know in any given case whether or not the requisite conditions have been supplied,—*i.e.* impoverished nutriment for an enormous length of time,—this newly added cause affords no further justification for the old statement, that the theory of Natural Selection fails to account for all the facts of Dysteleology.

The perusal of the last-mentioned thoughtful conception has suggested to me the probable existence of another cause, having a more general application; but as it can never induce complete suppression, I shall reserve it for the subject of another communication.

Mr. Mivart supposes that organs may become suddenly aborted ‡; but, apart from the weighty objections to this view,§ there is no case on record, so far as I am aware, of an organ thus becoming *totally* suppressed in any domestic species. A sport of this kind always leaves a rudiment, and it is upon the analogy of such sports alone that Mr. Mivart's argument is founded.

Having now enumerated all the causes ever proposed by evolutionists to account for the reduction of useless parts, it is evident that we should antecedently expect to find innumerable examples of such parts in the condition of rudiments.‖ Indeed the only difficulty is to account for that final disappearance of organs which must, by any theory of evolution, be postulated to have taken place. The solution is afforded by the exhaustive contemplations of Mr. Darwin, for, whether or not we believe in pangenesis, we cannot but deem it in the highest degree probable that the influence of inheritance is not of unlimited duration. If so, we have at once an adequate cause for the eventual destruction, even in the embryo, of rudimentary parts; but, as it is a cause which would only act after an immense lapse of time, it would have no influence until the original specific type had undergone a considerable modification. Thus, the facts of dysteleology, far from "cutting two ways," afford the strongest confirmation of the natural selection theory; for, as time is thus shown the chief agent in the final destruction of rudiments, and as species are always undergoing change, on the one hand we have an explanation of the fact, that the greater the divergence of the specific type from its original the fewer rudiments do we find of organs characteristic of the latter, while on the other hand, the less such divergence the greater the number of such rudiments—a fact of which the necessary consequence is, that "with species in a state of nature, rudimentary organs are so extremely common that scarcely one can be named which is wholly free from a blemish of this nature."

GEORGE J. ROMANES

upon until the point of such exhaustion is attained; but is it not open to question whether this point can never be reached at all? It must de remembered, too that in the case of wild species the effects of disease are always associated with other reducing causes, so that here we may easily over-rate the share it has in the work; but in the case of domesticated species the effects of disease are much more isolated (in consequence of Economy of Growth, etc., being, to a great extent, in abeyance); and here we find that atrophy of disused parts, although at first very rapid, eventually does not proceed to nearly so great an extent as it does in the case of wild species. The question thus raised, however, is of no practical importance, since whether or not disuse is the chief *cause* of atrophy in species, there is no doubt that atrophy *accompanies* disuse.

* "Variation," vol. ii. p. 80.

† "Variation," vol. ii. p. 397.

§ See "Origin," pp. 201—204.

‖ It is unnecessary to consider the *collective* action of these causes, for a moment's reflection will now make it evident that none such exists below the point at which the Economy of Growth ceases to be felt.

The Action of the Heart

HAVING replied to Mr Garrod's criticism of my "Locomotion of Animals" (NATURE, vol. ix. p. 281), I now wish to show that the explanation given by him of the diastole of the heart is not in accordance with fact.

In a recent number of NATURE (vol. ix. p. 282) I asked Mr. Garrod to explain "how the left ventricle of the heart opens after a vigorous contraction in which all the blood contained in the ventricular cavity is ejected and the ventricle converted into a solid muscular mass, if not by a spontaneous *elongation* of all its fibres." He replies:—"At first sight it might seem that the active dilatation of the heart during the diastole did depend on an inherent power in the muscular fibres of the ventricles to elongate, but the peculiarities of the coronary circulation are quite sufficient to explain the phenomenon without the introduction of so unnecessary a theory as that of Dr. Pettigrew. For in the heart when removed from the body, as in the living body during diastole, the injection of fluid into the coronary vessels causes the whole heart to open up from the congestion of the ventricular walls, and so produce the active dilatation which is well known to occur" (NATURE, vol. ix. p. 301).

The explanation given by Mr. Garrod of the manner in which the ventricles of the heart open up during the diastole is eminently unsatisfactory. In fact it is no explanation at all. He informs us that the active dilatation of the ventricles is due "*to peculiarities in the coronary circulation*" . . . "for in the heart when removed from the body the injection of fluid into the coronary vessels causes the whole heart to open up from the congestion of the ventricular walls, and so produce the active dilatation which is well known to occur."

The coronary vessels, as everyone is aware, simply supply the blood which nourishes the substance of the heart. There is no peculiarity whatever in the circulation of the blood through them. The blood flows through the coronary vessels in a more or less steady stream as through all the other vessels of the body. In other words the substance of the heart is full of blood during the closure or systole of the ventricles, as well as during the opening or diastole of the ventricles. The presence of the blood, therefore, within the coronary vessels can exert no influence in opening up or actively dilating the ventricles. This is proved by direct experiment. If the heart be cut out of the living body and the coronary vessels divided, the ventricles go on opening and closing with the utmost regularity for protracted periods. Here, however, the power which, according to Mr. Garrod, opens the ventricles is inoperative. The same thing happens when the heart is cut out of the body and the vessels laid open. If, however, the ventricles open and close when the coronary vessels are freely divided, and the blood which is said to distend or open up the ventricles is allowed to escape from the cut surfaces, it is quite clear that the blood pressure within the ventricular walls can exert no influence whatever in producing the diastole. If blood is not admitted into the coronary vessels, or if admitted it is allowed freely to escape, it cannot of course act as a distending medium. Allowing, however, for the sake of argument, that the flow of blood through the vessels of the ventricles occasioned the opening or dilatation of the ventricles, it is evident, for the same reason, that the presence of the blood within the ventricular walls, from the fact that the blood is nearly constant in quantity and virtually incompressible, would prevent the closing or contraction of the ventricles. Mr. Garrod, I opine, is

here on the horns of a dilemma. He evidently puts the cart before the horse. It is the movements of the heart which determine the movements of the blood, and not the converse.

The cardiac movements are due to a change of shape in the sarcous elements or ultimate particles of the muscular fibres of the heart, and in the adult organ can only be effected by a vital and alternate elongation and shortening of all the fibres composing the heart; the elongation occurring during the diastole and the shortening during the systole. Similar remarks are to be made of the voluntary muscles which, as stated in my work on "Animal Locomotion," are endowed with centrifugal and centripetal movements.

That the opening and closing of the ventricles of the heart are in no way connected with the passage of blood through the substance of the organ, is proved indirectly by the movements of the heart of the embryo. Here the heart opens and closes with time-regulated beat, while yet a mass of cells, and before it contains blood either in its cavities *or in its substance.* But that the presence of blood is not necessary to such movements is placed beyond doubt, for rhythmic movements occur in the vacuoles of certain plants, as *e.g.* the *Volvox globator*, *Gonium pectorale*, and *Chlamydomonas*, where no blood is present.

Lastly, if a frog be slightly curarised and its spinal cord destroyed, it is found, on exposing the heart, that the sinus venosus, vena cava inferior, the auricles and ventricles *are quite destitute of blood*, and yet the organ beats normally and with the utmost regularity. Mr. Garrod has consequently not yet succeeded in answering my query as to how the diastole of the left ventricle is produced He has failed to show that it is not effected by the *active elongation or centrifugal movements of all its fibres.*

J. BELL PETTIGREW

Lakes with two Outfalls

HAVING observed the discussion lately carried on in your pages as to the existence of lakes with two outfalls, I think the following description of such a lake by Prof. Bell, of the Geological Survey of Canada, may be interesting to some of your readers. It occurs on the summit of the high Laurentian country between Lake Superior and Hudson's Bay:—

"In crossing the country from Lake Nipigon to the Albany River, we first followed the Ombabika River to its source, which is in Shoal Lake, three and a half miles long and one mile wide, lying at a distance of twenty-five miles north-east of the mouth of the river. This lake lies due north and south, and discharges both ways, the stream flowing northward towards the Albany, called the Powitik River, being nearly as large as the southern outlet. No portage occurs on the Ombabika for about nine miles before reaching Shoal Lake, nor for nearly five miles beyond its northern outlet; so that we passed the height of land with the greatest possible ease, having had about seventeen miles of uninterrupted canoe navigation, from the time we made the last portage, in going up the southern side, till we came to the first on going down on the northern. Shoal Lake has an elevation of scarcely 300 ft. over Lake Nipigon, or about 1,200 ft. above the sea."—"Report of Progress Geological Survey of Canada for 1871-72," p. 107.

GEORGE M. DAWSON

Montreal, Feb. 19

The Ink of the Cuttle-fish

WITH reference to the interesting account in NATURE, vol. ix. p. 332, of a gigantic Cephalopod captured in American waters, and of a still larger one, which attacked the boat belonging to some fishermen near Newfoundland, by twining its arms round the vessel, and which, having had two of those arms cut off by the fishermen, moved off, "ejecting a large quantity of inky fluid to cover its retreat," I desire to draw attention to an observation respecting this fluid, which I made on the occasion of a visit to the Crystal Palace Aquarium. My friend Mr. Lloyd was good enough to dislodge a cuttle from its place of concealment, and the usual inky discharge followed, as the creature shot across the tank. Mr. Lloyd states in his interesting "Handbook to the Marine Aquarium," "that the ink (which is viscid) does not generally become diffused through the water as writing ink would be, but is suspended in the water in a kind of compact cloud till it gradually settles down, and is dispersed in flakes." Now I quite think, with Mr. Lloyd, that this being the case, it is difficult to perceive how, according to the generally received opinion, its retreat is covered by the ejected cloud. It seems to me more likely that this discharge is to divert the attention of a pursuer—a dog-fish for instance—which would for the moment be startled by the sudden appearance of masses of dark colour in the water, and in the confusion the cuttle makes his escape.

Now that public aquaria are becoming so general in our great towns, it is much to be hoped that this and many other interesting problems in marine zoology may be solved.

Birmingham, Feb. 28

W. R. HUGHES

Transmission of Light in a Squall

ON the Admiralty Pier, Dover, during a "squally" gale, I remarked an occasional jerking or unsteadiness in one of the adjacent lights, say two miles off, to one of the coast-guard's men with whom I was talking at the time.

To him this was a well-known observation in squally weather. At times, he said, two lights could distinctly be seen for a second or so; frequently the shape of the light was changed, by elongation, vertically and horizontally.

The above phenomenon, if not generally known, might be worth noticing and verifyin in your excellent paper.

I suppose an explanation is to be found in the different densities of the atmosphere through which a ray of light must pass in rough unsteady weather; the second image being simply the persistence of the one seen immediately before the change in position of the ray by refraction.

JAMES C. INGLIS

DR. LIVINGSTONE AND THE CAMERON EXPEDITION

IN NATURE for Feb. 26, we expressed the desire which we felt, in common with our readers, for information respecting the orders that have been sent to Zanzibar as to the disposal of Dr. Livingstone's body. We now have great pleasure in being able to announce that Lord Derby acted with the promptitude and energy which might be expected from a statesman who has always shown a warm sympathy for the cause of geography. With the concurrence of the family, his Lordship has sent a telegram ordering the body of the illustrious traveller to be sent to England, and we believe that it is to be accompanied by one or two of Livingstone's faithful negro followers.

The melancholy death of Dr. Dillon and the return of Lieut. Murphy, leaves Lieut. Cameron alone, to proceed to Ujiji, to recover the box of papers left there by Livingstone, and to prosecute further geographical exploration. Heavy unforeseen expenses obliged Lieut. Cameron, who has proved himself to be a resolute and observant explorer, to purchase stores at exorbitant rates at Unyanyembe. The necessity for providing for the march of Murphy and Dillon to the coast, with Livingstone's body and most of his followers, is his complete justification for incurring this unauthorised expenditure, and there can be no doubt that the Geographical Society will treat its gallant emissary in a generous and liberal spirit. Cameron has suffered cruelly from fever and ophthalmia, and he is now resolutely pressing onwards in the performance of his work—the Society's work—in the face of greater difficulties than were encountered by any previous expedition. He carries with him our warmest wishes for his success, and the sympathy of every true geographer in England.

ON THE NEW RHINOCEROS AT THE ZOOLOGICAL GARDENS

A GLANCE at our list of additions to the Zoological Gardens during the last week will inform the reader that the Zoological Society has been successful in adding to its already unrivalled collection of specimens of the genus Rhinoceros still another species, which is exhibited for the first time in the Society's collection, and most probably in this country.

It is well known amongst naturalists that in Asia there are to be found two species of Rhinoceros, with a single horn developed on the top of the nose. The

larger of these is the gigantic Indian Rhinoceros (*R. unicornis*), many specimens of which have been brought to this country, and a very fine male example of which is living in the Regent's Park Gardens. In it the skin, which is immensely thick, is thrown into massive folds or shields, making the animal appear as if clad in armour-plating. Each shield is thickly studded with nearly circular slightly-raised tubercles, which look very much like the heads of innumerable bolts intended to strengthen and retain the shield in position. The folds that surround the neck, where it joins the head, are very ample, producing the appearance of the now so fashionable ruff, somewhat modified. According to the observations of the late Mr. Edward Blyth, the Indian Rhinoceros is found only at the foot of the Himalayan hills, and in the province of Assam, along the valley of the Brahmapootra.

The second species of one-horned Rhinoceros is generally called the Javan Rhinoceros (*R. sondaicus*). It is found in Java, and in the country stretching from Malacca up through Burmah to Assam. It is considerably smaller than the Indian species; the shields are not so strongly marked, and are not arranged in an exactly similar manner, the gluteal shield not being completely divided into two by a transverse fold situated half-way down it; and the middle neck fold, instead of running backwards on each side before it reaches the spine, crosses the middle line, and so divides off a saddle-shaped shield, which is median, and as deep from before backwards as from side to side. The fold which surrounds the neck is also much less significant, and the head is narrower and less formidable in aspect. The tuberculation of the shields is more slightly marked, and each tubercle is proportionately smaller in diameter.

It is a specimen of this Javan Rhinoceros (*R. sondaicus*), a nearly full-grown male from Java itself, which the Zoological Society has succeeded in purchasing, and which is now exhibited in the same house as the Indian species, so that every opportunity is at last afforded for a more minute study of the differences which will most probably be found to distinguish the two species.

The other species of Asiatic Rhinoceroses, namely, the Sumatran Rhinoceros (*R. sumatranus*), and the Hairy-eared Rhinoceros (*R. lasiotis*), are both two-horned, and have been divided off as a separate genus, that of *Ceratorhinus*, by Dr. J. E. Gray. The skin is not divided into shields, and is thinner than in the one-horned species. The type specimen of the Hairy-eared Rhinoceros, the only example known, is now living in the Zoological Gardens. About a year ago the Sumatran animal was also represented, and rumour says that the gap caused by its loss will not be long unfilled.

NEIL ARNOTT, M.D., F.R.S.

WE have this week to record the death of this well-known man of science, which took place at his residence in Cumberland Terrace, Regent's Park, on the 2nd inst. He was born at Arbroath in May 1788, and had consequently reached his eighty-sixth year.

While Neil was yet young his father died, and the family removed to Aberdeen. Neil went to the Aberdeen Grammar School, being there with Lord Byron, and succeeded so well in the one thing then taught, Latin, that he gained a bursary by a competition in Marischal College, which he entered in 1801. In his third year he came under Patrick Copeland, Professor of Natural Philosophy, renowned for his admirable course of lectures, and especially for his power of experimental illustration. Arnott was one of Copeland's best pupils, and afterwards turned to full account the careful notes that he had made of the lectures.

He began the study of medicine in Aberdeen, and in 1806 he went to London to prosecute the study. Young Arnott, while his medical education was still incomplete, went aboard an Indiaman, as assistant-surgeon, making the usual voyage of a trading East Indiaman in those days. He was the intellect and soul of the ship, associating with everyone that could learn or teach anything; he was the resource in all serious emergencies, of whatever kind.

On his return to England, in 1811, he settled as a medical practitioner in London. He was the chief medical adviser to a colony of French refugees who settled in Camden Town, and also became physician to the French and Spanish Embassies, his fluency in languages serving him in good stead. It was about 1823 that he first turned to account his studies in natural philosophy, by giving in his own house a course of lectures both on the general subject and on its applications to medicine. These lectures formed the basis of the "Physics," the first volume of which appeared in 1827, and gained for the author an instantaneous and wide-spread reputation. The first edition was sold in a week after being reviewed by the *Times*. In a few years five editions were exhausted, and the work was translated into all the languages of Europe. The freshness and popular character of his style recommended the book to the general public, and did not prevent its favourable reception by the highest scientific authorities; Herschel and Whewell both gave emphatic testimonies to its accuracy and originality. The author was thenceforth recognised as a man of science and an inventor of no mean order. His practice as a physician was extended, and he became a Fellow of the Royal Society. On the foundation of the University of London in 1836 he was nominated a member of the Senate, and in 1837 he was named Physician Extraordinary to the Queen.

In 1838 he published a treatise on warming and ventilating, and in this he described the stove since called by his name. He introduced the water-beds, and made many other useful applications of physics to medical and surgical practice. For many years he had withdrawn from medical practice. He had a large circle of friends in and out of the profession. His conversational powers, his large range of scientific knowledge, and his geniality of manner, will be long remembered by those who now regret his loss.

OZONE *

II.

SOME of the properties of ozone have already been referred to. At the common temperature of the atmosphere, it may be preserved, if dry, for a very long time in sealed tubes, but by slow degrees it becomes changed again into ordinary oxygen. This conversion goes on more rapidly as the temperature is raised, and at 237° C. it is almost instantaneous ("Phil. Trans." for 1856, p. 12). The alteration of volume which occurs at the same time has been already sufficiently described. A similar effect to that of heat is produced by several oxides, such as the oxide of silver or the peroxide of manganese, which by contact, or, as it is termed, catalytically, instantly change ozone into ordinary oxygen. Ozone is also destroyed by agitation with water, provided the ozone is in a highly diluted state. But the most interesting fact of this kind is one which I have recently observed, and which I hope to be able to exhibit to the Society. Dry ozone, even if present in such quantities as freely to redden iodide of potassium paper, is readily destroyed by agitating it strongly with glass in fine fragments, although, as we have seen, it may be preserved for an almost indefinite period in sealed glass tubes. This experiment, as it appears to me, forms a new and closer link than any hitherto observed between a purely mechanical action and a chemical change.

Ozone is a powerful oxidising agent. It attacks metallic mercury and silver with great energy, and converts them into oxides. The experiment with mercury is very striking, and is a delicate test for ozone, either in the dry or moist state. A few bubbles

* An Address delivered before the Royal Society of Edinburgh on December 22, 1873, by Dr. Andrews, LL.D., F.R.S., Honorary Fellow of the Royal Society of Edinburgh. (Continued from p. 340.)

of oxygen containing not more than $\frac{1}{100}$th part of ozone will alter wholly the physical characters of several pounds of mercury, taking away the lustre and convexity of the metallic surface and causing the mercury to form an adhering mirror to the surface of the glass vessel in which it is contained. If ozone in a diluted state is slowly passed through a tube filled with silver leaf, the metal will be oxidised to the distance of 2 or 3 millimetres, but the oxidation will not proceed further, although the ozone reactions are wholly destroyed. This striking result is due to the catalytic action of the portions of oxide which are first formed. So small is the amount of oxide produced in this case that, in a glass tube through which many litres of electrolytic ozone had been passed, the increase in weight from the formation of oxide only amounted to a scarcely appreciable fraction of a milligramme.

Ozone is absorbed by oil of turpentine, oil of lemon, and other essential oils. These oils have also, like phosphorus, the power of changing oxygen into ozone, while they are slowly oxidising; so that if oil of turpentine is shaken for some time in a flask filled with air or oxygen, the oil will acquire ozone properties.

Ozone decomposes a solution of iodide of potassium, liberating the iodine, which may be discovered by its red colour, or its blue compound with starch. If the action is continued sufficiently long, the free iodine disappears from the formation of iodate of potassium and the solution becomes colourless. Reddened litmus paper moistened with a solution of iodide of potassium is turned blue, when exposed to the action of ozone, in consequence of the caustic alkali formed by the decomposition of the salt. In employing this test it will often be found advantageous to remove the free iodine by washing the paper with strong alcohol. This form of the iodide of potassium test has been proposed by Houzeau for the discovery of ozone in the atmosphere. Ozone produces other reactions of a similar character which it will be sufficient here barely to mention. Paper moistened with sulphate of manganese becomes brown when exposed to this agent from the formation of the hydrated peroxide. Solutions of thallous oxide are in like manner converted into the brown peroxide; the black sulphide of lead into the white sulphate, and the yellow ferrocyanide of potassium into the red salt. The action of ozone on tincture of guaiacum, which it turns blue, was made a subject of special study by Schönbein.

The bleaching properties of ozone are highly characteristic and have attracted a great deal of attention. It deprives indigo of its blue colour, converting it into isatin, and bleaches readily litmus and other vegetable colouring matters. Attempts have been made to apply this property of ozone in the arts, and particularly to the refining of sugar and the bleaching of linen. It has been even stated that these and other applications of ozone, as a decolorizing or bleaching agent, have been successful; but the results of my inquiries on this point have, I regret to say, been unfavourable, and it remains yet to be seen whether this singular body can be made subservient to the useful purposes of life. For the preparation of ozone on the large scale from ordinary air, a modification of the tube-generator of Siemens has been proposed by Beanes, and is an efficient and powerful instrument.

I will not detain the Society by an account of the history or properties of the problematical body to which Schonbein gave the name of antozone. He considered this body to be oxygen possessing permanently positive properties, while ozone itself he regarded as negative oxygen. Ordinary or inactive oxygen, according to him, is formed by the union of ozone and antozone. These views have not been supported by recent investigations, which leave little doubt that the antozone of Schönbein is identical with the peroxide of hydrogen of Thénard. From ozone the peroxide of hydrogen can be readily distinguished by the solubility of the latter in water.

Soon after the discovery of ozone, Schonbein having observed that the air of the country frequently coloured a delicate ozone test-paper in the same manner as ozone itself, inferred that ozone is a normal constituent of our atmosphere. He concluded that the amount of this body present in the air is different in different localities, and in the same locality at different times, and with great boldness he attempted to connect its presence or absence with the prevalence or rarity of certain catarrhal affections. A new field for investigation was thus opened up, which has been assiduously cultivated by a large and zealous band of observers. Before referring however to their labours, it will be necessary briefly to allude to the present state of our knowledge regarding the existence of ozone in the atmosphere.

Schönbein always maintained that ozone is a constituent of atmospheric air, and his various papers on this subject alone would, if collected, fill a large volume. In his last memoir he observes that the active substance in the air acts in a parallel manner on iodide of potassium and sub-oxide of thallium papers, although more slowly on the latter; and that the thallium paper, which has been coloured brown by the air, behaves towards reagents in the same manner as that which has been exposed to artificial ozone. From these facts he infers that the active substance in the air is neither peroxide of nitrogen nor sulphuretted hydrogen. He further states that the atmosphere never contains free nitric acid, although nitrate of ammonium in small quantities is frequently present; and that neither chlorine nor bromine can be present in the free state in air, on account of their affinity for hydrogen. Houzeau also maintained that the existence of ozone in the air was proved by the alkaline reaction of iodide of potassium paper, which had been decomposed by exposure to the atmosphere. Although experiments and arguments of this kind were sufficient to give probability to the view that the active substance in the atmosphere which produces these reactions is ozone, they were at the same time far from conclusive, and some of the ablest chemists of Europe accordingly considered the question doubtful, while others attributed the effects observed to the presence of oxidising agents altogether different from ozone. I will only cite on this point the opinion of M. Frémy, whose researches in conjunction with M. Becquerel on ozone have already been referred to. "Without denying," he remarked at a meeting of the Academy of Sciences in 1865, "the importance of the indications given by the paper of M. Schonbein, or by that of M. Houzeau, I do not find that these reactions demonstrate with sufficient certainty the existence of atmospheric ozone. I am of opinion that the presence of ozone in the air must be established anew by incontestable experiments"

In 1867 I made a set of experiments which I had contemplated some years before for the purpose, if possible, of finally settling this important question. The method I proposed was to ascertain whether, in addition to the power of decomposing solutions of iodide of potassium and of certain other salts, the active body in the atmosphere possessed the other properties of ozone, some of which are highly distinctive. The inquiry was a delicate one, in consequence of the very minute quantity of the active body which is present, even under the most favourable conditions, in atmospheric air. The results of this investigation are given in a short note which was published in the "Proceedings of the Royal Society" for 1867. (1) By passing a stream of atmospheric air, which gave the usual reaction with iodide of potassium paper, for some hours over the surface of mercury in a U-tube, the metal was distinctly oxidised. (2.) The ozone reactions disappeared when the air was passed through a tube containing pellets of dry oxide of manganese. The experiment was continued till 80 litres of air had traversed the manganese tube without producing the slightest discoloration of a delicate test-paper. (3.) But the crucial experiment was to ascertain whether the active body in the air loses its characteristic properties, or is destroyed, at the same temperature (237° C.) as ozone. To determine this point, a stream of atmospheric air, which gave strong ozone reactions, was passed through a globular glass vessel (Fig. 5), covered with wire gauze, of 5 litres capacity, and afterwards through a U-tube 1 metre in length, whose sides were moistened internally with water, while the tube itself was kept cool by being immersed in a vessel of cold water. After traversing the globular vessel and the moistened U-tube, the air was blown over a slip of delicate test-paper, in order to ascertain the presence or absence of ozone. When the atmospheric air was drawn through this apparatus at a uniform rate by means of an aspirator raised by clockwork, the iodide of potassium paper was distinctly reddened in two or three minutes, provided no heat was applied to the glass globe. But on heating the air as it passed through the globe, to a temperature of about 260° C., not the slightest action was produced on the paper, however long the current of air continued to pass. On the other hand, when air free from ozone, but containing traces of chlorine or of the higher oxides of nitrogen, was drawn through the apparatus, the test-papers were equally affected, whether the globe was heated or not. These experiments have since been successfully repeated by Dr. C. Fox.

The identity of the active body in the atmosphere with ozone we may now assume to be established beyond dispute, and the accuracy of Schonbein's views on this subject to be fully con-

firmed. To determine, however, the actual amount of ozone in the atmosphere is a problem of surpassing difficulty, on account of the extremely small proportion in which it exists, even when at a maximum. Its presence can be easily discovered by any of the ordinary iodised starch-papers, or even more readily by white bibulous paper which has been moistened with a dilute solution of iodide of potassium, and allowed to dry spontaneously in a dark room. If a slip of this paper is exposed for five minutes to a current of air, which will be often supplied by the wind, or may be produced by walking briskly, it will be found to have acquired a delicate red tint, if ozone be present even in the smallest quantities. The tint will be best observed by comparing the slip after exposure with another slip of the same paper which has not been exposed. The action of the diffused light of day on the paper is rarely perceptible after so short an exposure, but this source of error can be easily avoided by enclosing the paper in a hollow cylinder of wood.

Although with the experimental resources now at our command, we can scarcely venture even to estimate the actual amount of ozone at any time present in the atmosphere, yet it may be possible, as Schönbein long ago proposed, by applying a chromatic scale to the indications of the test-papers, to ascertain approximately its relative amount in different localities, and its variations in the same locality. Such estimates must, however, be most uncertain, since the shades of colour produced on test-paper hardly admit of being defined by numbers ; and in this particular case they are liable to a special source of error, as there can be little doubt that a large but unknown part of the ozone in

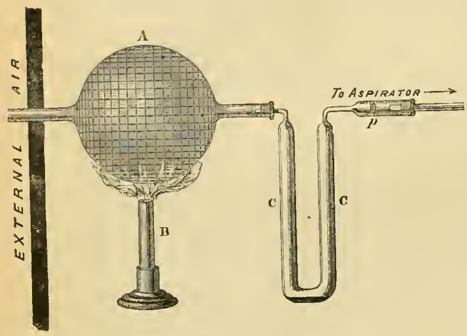

FIG. 5.

the air which comes into contact with the paper is catalytically destroyed, and produces no chemical effect whatever. At the same time the ozonometer, especially when used with an aspirator, does unquestionably give indications of value regarding the ozone states of the atmosphere, and till more accurate methods are devised these observations ought certainly to be continued.

Ozone is rarely found in the air of large towns, unless in a suburb when the wind is blowing from the country ; and it is only under the rarest and most exceptional conditions that it is found in the air of the largest and best ventilated apartments. It is, in fact, rapidly destroyed by smoke and other impurities which are present in the air of localities where large bodies of men have fixed their habitation, and I have often observed this destructive action extending to a distance of one or two miles from a manufacturing town, even in fine and bright weather.

Ozone is rarely, if ever, absent in fine weather from the air of the country, and it is more abundant, on the whole, in the air of the mountain than of the plain. It is also said to occur in larger quantity near the sea than in inland districts. It has been found to an unusual amount after thunderstorms—a fact which is favourable to the view that the presence of ozone in the atmosphere is due to the action of the free electricity of the latter on the oxygen of the air. The amount of ozone in the air is greater, according to some observers, in winter than in summer, in spring than in autumn ; according to others, it is greater in spring and summer than in autumn and winter. As regards the influence of day and night, the observations do not all tell the same tale. Ozone has usually been found more abundantly in the air at night than by day, but some careful observers have found the reverse of this statement to be true.

Schönbein was the first who attempted to connect the fluctuations of atmospheric ozone with the prevalence or absence of epidemic disease ; and since this suggestion was first published, numerous observations have been made in different countries with the view of ascertaining whether there is really any connection between the indications of the ozonometer and the health of a district. It has been asserted, for example, as the result of observation, that an outbreak of cholera is accompanied by a marked diminution of atmospheric ozone ; but this statement has been disproved by later and more trustworthy observations. On the whole, I think it may be safely asserted that no connection has yet been proved to exist between the amount of ozone in the atmosphere and the occurrence of epidemic or other forms of disease.

The permanent absence of ozone from the air of a locality may, however, be regarded as a proof that we are breathing, if I may venture to use the phrase, adulterated air. Its absence from the air of towns, and of large rooms, even in the country, is probably the chief cause of the difference which every one feels when he breathes the air of a town, or of an apartment however spacious, and afterwards inhales the fresh or ozone-containing air of the open country. It is, indeed, highly probable that many of the most important actions, by which the products of vegetable and animal waste are removed by oxidation from the air, are due to the action of ozone, and could not be effected by ordinary or inactive oxygen. If the amount of ozone in the atmosphere appear too small to produce such large results, we must remember that, from its powerful affinities, ozone is being continually used up, and must, therefore, be constantly renewed.

The physiological action of ozone on the animal system is a subject of interest, and I am able to state the general results of two independent inquiries—one conducted a few years ago, by Dr. Redfern, in Queen's College, Belfast, the other recently communicated to this Society by Mr. Dewar and Dr. McKendrick. Dr. Redfern's experiments have not been published, but he has kindly supplied me with the following note on the subject :—"The general results," he says, "I obtained from about forty experiments conducted from May to September, 1857, to find the effects of oxygen and ozone on different animals, are as follows. The respiration for a very short time of oxygen, containing about $\frac{1}{240}$th part of ozone, is certainly fatal to all animals. The same gas, when passed over peroxide of manganese and freed from ozone, is comparatively harmless, even when respired for long periods. Respiration of such a mixture of ozone for thirty seconds kills small animals, some dying after respiring it only fifteen seconds, whilst similar animals will live in good health for months after respiring oxygen alone for thirty-seven hours, the carbonic acid being removed during the experiment. Death is not due to the closure of the glottis, for it occurs when a large opening has been made in the trachea. Ozone causes death by producing intense congestion of the lungs with emphysema, and distention of the right side of the heart with fluid or coagulated blood, frequently attended by convulsions. If ozone be respired in a dilute form, the animals become drowsy and die quietly from coma, the condition of the lungs and heart being the same, except that the emphysema is less marked. Animals which have respired oxygen for more than twelve hours will now and then die suddenly from the formation of coagula in the heart, even after they have appeared in good health for some days."

The following are the conclusions which Mr. Dewar and Dr. McKendrick have deduced from their researches. Inhalation of an atmosphere highly charged with ozone diminishes the number of respirations per minute, and reduces the cardiac pulsations in strength, the temperature of the animal being at the same time lowered from 3° to 5° C. After death the blood is found to be in a venous condition. Neither the capillary circulation nor the reflex activity of the spinal cord is appreciably affected. The same remark applies to the contractility and work-power of the muscles. Ozone acts on the coloured and colourless corpuscles of the frog like carbonic acid. Ciliary action is not affected by ozonised air or oxygen, but if the layer of liquid be very thin, the cilia are readily destroyed.

The thermal changes which accompany many of the reactions of ozone are well marked, and their investigation, which has been undertaken by Mr. Dewar, promises to yield a valuable addition to our thermo-chemical knowledge.

THE COMMON FROG*

XI.

THE eye of the frog is a beautiful and brilliant object, and relatively large. It is furnished with two eyelids, but, unlike those of man, it is the inferior one which is the more movable. In addition to these it is defended by a third eyelid, called the victitating eyelid, which is similar to that one which may be seen (if watched for) so frequently and rapidly to cross the eye of birds, *e.g.* of a hawk.

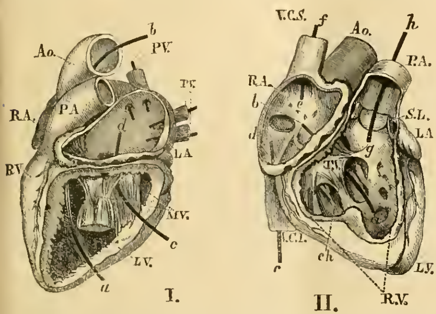

FIG. 74.—I. The left side; and II. the right side of the Heart dissected. I.—*LA*, the left auricle; *PV*, the four pulmonary veins; *cd*, a style passed through the auriculo-ventricular aperture; *MV*, the mitral valve; *ab*, a style passed through the left ventricle into the aorta; *RA*, *RV*, parts of the right side of the heart; *PA*, pulmonary artery.
II.—*RA*, the right auricle; *VCS*, superior vena cava; *VCI*, inferior vena cava, the styles *fe*, *cd*, being passed through them into the auricle; *ab*, style passed through the auriculo-ventricular aperture; *TV*, tricuspid valve; *RV*, right ventricle; *SL*, semi-lunar valves at the base of *PA*, the pulmonary artery, through which the style *gh* is passed; *LA*, *LV*, auricle and ventricle of the left side of the heart.

This structure, however, is no mark of affinity to birds, as it is one which reappears, when wanted, in widely different forms. Thus we find it in the whale, *i.e.* in the

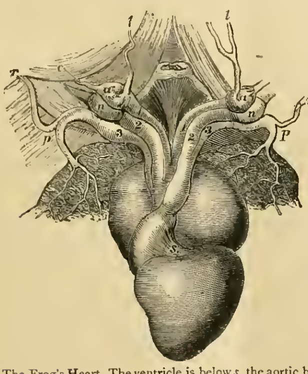

FIG. 75.—The Frog's Heart. The ventricle is below *s*, the aortic bulb is on the left of *s*, and ends in six aortic trunks, three on each side. The first of these (1), ends in the carotid gland (*a*), whence spring the lingual (*l*), and the carotid (*c*), arteries. The second trunk (2), is the root of the great dorsal aorta. The third trunk (3), ends in the pulmo-cutaneous artery (*r*), and the pulmonary artery (*p*), which is shown sending ramifications over each lung.

highest class of the Vertebrate sub-kingdom, and in certain sharks, *i.e.* in the lowest class of the same.

Eyelids do not exist in all members of the frog's class. Even in its order they are extremely minute, in *Pipa* and *Dactylethra*, which have very small eyes. In *Amphiuma* they are completely wanting, and in *Proteus* and in the *Ophiomorpha* the minute eyeballs are covered with the ordinary and unchanged skin of the head.

The ear of the frog's class presents us with the incipient condition of that part as an organ destined to respond to sonorous vibrations conveyed to it by the atmosphere.

In man the internal ear (enclosed in the densest bone

FIG. 76.—Section of heart. *a* and *b*, openings of the auricles into the ventricle; *c*, opening of the aortic bulb into the ventricle.

of the skull, named, from its density, "petrous") is a very complex organ. The aperture, surrounded by the folds of the external ear, leads by a canal towards a cavity called the tympanic cavity, which cavity is shut off from the exterior by the tympanic membrane (or drum of the ear), which stretches across the canal at a considerable distance from its external aperture. On the inner side of the tympanic cavity lie the convoluted tubes (richly supplied with nerves) which constitute the real organ of hearing or internal ear.

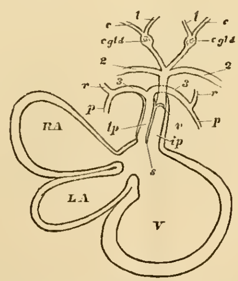

FIG. 77.—Diagram of section of Frog's heart. *LA*, left auricle; *RA*, right auricle; *V*, ventricle; *s*, movable septum dividing the left aortic passage *lp* from the right aortic passage *ip*; *v*, valve; 3, 3, aortic trunks leading to *p*, pulmonary artery and *r*, cutaneous respiratory artery; 2, 2, aortic trunks going to form the great dorsal aorta; *cgld*, carotid gland interrupting the flow of blood into *l*, the lingual artery, and *c*, the carotid artery.

Although the tympanic cavity is shut off from the exterior by the tympanum, it nevertheless is not altogether shut off from the exterior, since it communicates with the back of the mouth by a long and narrow canal termed the Eustachian tube.

It is the existence of these Eustachian openings into the

* Continued from p. 307.

ear from the mouth which causes people when intently listening to keep their mouth slightly open.

In the frog there is no such external canal, but the tympanum is plainly to be seen in the way already described, on the side of the head, covered only by a slightly striated portion of the skin of the body. The Eustachian tube, however, still exists in the frog, though it is short and wide, and the opening of each is to be seen on one side of the back of the mouth.

This condition of things, however, does not exist in all the members of the frog's order, still less of his class. But in *Proteus*, *Siren*, and *Menobranchus* there is no tympanic cavity whatever, and the organ of hearing is simply imbedded in the skull, and probably responds but to sonorous vibrations conveyed to it by the denser aquatic medium, and not at all, or but very imperfectly, to those of the atmosphere.

In the ordinary efts we still meet with an Eustachian canal, but the tympanum is absent.

In the frog's own order, as in *Pelotates* and *Bombinator*, we may fail to find any tympanum, while the Eustachian tubes are all but obliterated, being reduced to the most minute dimensions.

Another condition, however, may be presented which offers a singular contrast, and is the more remarkable from the widely separated geographical situations of the forms which present it. In the South American *Pipa*, as well as in the South African *Dactylethra*, the two Eustachian tubes run together and open at the back of the mouth, by a median and common aperture.

Strange to say, this is the very condition which exists in birds, though most certainly it cannot be taken as any sign of affinity. In the crocodile these tubes have also a common median opening, but, unlike birds, each tube has also its own lateral opening into the throat, so that there come to be three Eustachian openings.

Can the resemblance between *Pipa* and *Dactylethra* in this matter be taken as a serious indication of genetic affinity, in spite of the wide, deep, and probably ancient Atlantic which rolls between the two species now?

This is a question which cannot be confidently answered, seeing in how many other instances structural peculiarities have evidently had an independent origin. Nevertheless, the fact that these two genera agree also in the small size of the eyes, rudimentary eyelids, and vastly expanded sacral transverse process would seem to point to some ancestral and fundamental relationship. If so, however, it is remarkable that no other such forms, or no intermediate ones should have been preserved, seeing that neither kind can be suspected of having migrated to its own habitat from the existing habitat of the other; and therefore that forms similar to that from which we may, if we please, conceive both to have been derived must have had a more or less widely extended geographical distribution and have been numerous in order to have given origin to genera in many respects so different as the two in question.

The Circulation of the Frog

Not only every animal, but every living being, requires, in order to carry on the functions of life, to interchange some of the gaseous elements of its body with gases of the medium (air or water) in which it happens to live.

Another function of extreme generality is that of conveying to all the parts and organs of the body nutritious matter for their growth or for the repair of those destructive effects which the processes of life inevitably produce in them.

In all members of the highest sub-kingdom of animals (*i.e.* in all Vertebrata) these processes of gaseous interchange and nutrition are effected by means of closed vessels, along which the stream of nutritious fluid (the blood) is continually carried in a definite and constant course. During some or other part of that course the blood becomes exposed to conditions specially favourable to the gaseous interchange, the blood parting with carbonic acid gas and obtaining in its place an increased supply of oxygen.

This process of blood oxygenation is termed respiration, and the organs which subserve it are termed respiratory or breathing organs. Such organs in man are the lungs. The central organ of circulation in man is, as all know, the heart, which is a muscular organ, divided into four chambers, or cavities.

These chambers are called "auricles" and "ventricles," and there are two of each—there being an auricle and a ventricle on the right side and also on the left.

Blood that has performed its nutritive functions, and is therefore charged with carbonic acid gas, is called venous blood, and is conveyed by the veins to the right auricle, whence it passes into the right ventricle, which sends it to the lungs for purification.

The oxygenated, or arterial blood, is returned from the lungs to the left auricle, and hence it is directly transmitted to the left ventricle, whence it is driven through the great artery (the *aorta*) into other arteries, and so distributed all over the body. The aorta passes downwards in front of the backbone, when it is called the *descending aorta*. Before turning downwards, however, it gives off great arteries to the arms and head, the *carotid arteries* carrying blood to the latter.

Now it is very important that the blood should not proceed in a direction the reverse of that indicated, and to prevent such misdirection, or regurgitation, special valves are placed at different openings; these valves freely allowing the blood to flow in the proper direction, but instantly opposing an effectual obstacle to a contrary flux.

The openings of the auricles into the ventricles are guarded by valves, as also is the opening of the left ventricle into the aorta, and that of the right ventricle into the artery going to the lungs.

The valve which guards the entrance into the right ventricle is called *tricuspid*, and consists of three flaps attached by delicate tendinous cords in such a way as to hinder the tending backwards of the flaps into the right auricle, and so allowing the blood to flow back into that chamber.

The valve which guards the entrance into the left ventricle is called *mitral* (from a fancied resemblance to a bishop's mitre), and consists of two flaps. The aperture leading from the left ventricle to the aorta is guarded by three crescentric flaps—called the "*semilunar*" valves of the aorta.

In man the whole of the blood is sent to the lungs for purification during each circuit of this most important fluid, and every organ is supplied with oxygenated blood.

If in any animals the process of purification is incomplete it is manifestly desirable that these organs of the body, the functions of which are the most important, should be supplied with that part of the blood which is pure. This consideration eminently applies to the brain, the director and controller of the entire body.

Now all birds and beasts without exception, share with man this perfect aëration of the entire blood, the whole of the blood in the classes *Mammalia* and *Aves* being purified in the lungs before being distributed to the body.

The conditions by which the frog, at the various stages of its existence, oxygenates its blood and directs the purified stream in the most desirable manner, are curious and instructive.

It is generally known that the lower air-breathing Vertebrates (Reptiles and Batrachians) have the heart less completely divided than in the higher classes, so that the oxygenated (or arterial) blood and the unoxygenated (or venous) blood become mixed in the single or imperfectly divided ventricle.

It might well be supposed, and in fact has generally

been so, that in animals with a heart so imperfectly divided, the blood sent to the lungs would be necessarily a mixture of venous and arterial fluid, and similarly that the blood distributed by it to all the organs and parts of the body is alike a mixture of pure and impure fluid.

In fact, however, this is by no means the case, and in the frog, in spite of the reception into a single chamber of both venous blood from the body, and of arterial blood from the lungs, special mechanical arrangements effect such a definite distribution of the two sorts of blood, that the unoxygenated fluid from the body is sent to the purifying respiratory surfaces (lungs and skin), and that the pure oxygenated blood alone goes to the head and to the brain.

For the detection of this beautiful mechanism, we are indebted to the careful investigations of Ernst Brücke.*

The heart of the frog consists of a right and left auricle (divided by a delicate septum), both opening into a single ventricle. From the latter proceeds an aortic root (bulbus aortæ) which gives rise to three arterial trunks on each side.

The first of these, or carotid trunk (1), ends in an enlargement (*a*) termed the carotid gland, of spongy structure, which gives rise to two arteries, one the lingual (*l*), the other (*c*), the carotid which goes to the head and brain.

The second, or systemic trunk (2) meets its fellow of the opposite side beneath the spine, and thence passes backwards as the great dorsal (in man descending) aorta, giving off arteries to all parts of the body.

The third, or pulmo-cutaneous trunk (3) ends by dividing into two arteries. The anterior of these (*r*) goes to the skin (which, as we have seen, is in the Frog an important agent in respiration), the posterior one (*p*) goes to the lungs.

The heart itself is of a more or less spongy texture, but the main cavity of the single ventricles open at its extreme right into that of the aortic bulb (*c*). In close proximity to the opening are the openings from the right (*b*) and the left (*a*) auricles respectively.

The aortic bulb is constitutionally divided by a movable septum (Fig. 77, *s*) in such a way, that the passage on the right side of it leads to the carotid and systemic arterial trunks, while the passage on the left side of it leads to the third pair of trunks—namely, those ending in the pulmonary and cutaneous arteries; moreover, there is a valve in the first of these two passages which tends to retard the flow of blood (*v*).

The consequences of these arrangements are as follows:—

When the auricles contract, the venous blood from the right auricle (*RA*) is sent into both right and left passages of the bulb, but by the action of the valve (*v*), and by the structure of the carotid gland, the blood is checked on the right side (*ip*), while on the left it runs freely into the pulmo-cutaneous trunks (*r* and *p*), and thus the respiratory structures receive unmixed venous blood for purification.

As the lungs get gorged with blood, the resistance on the two sides of the septum of the bulb becomes at first equalised and soon becomes the greater on the left side; then the septum is forced over to the left, and the blood, now mixed with pure blood, flowing in from the left auricle, flows freely along the systemic arteries (2 and 2). The obstruction of the carotid glands (*c gld*) being the greatest and the last to be overcome, the carotid and lingual arteries (*c* and *l*) receive the very last of the blood—that, namely, which coming from the left auricle is purely arterial—and in this way oxygenated blood only is supplied to the head, sense organs, and brain.

It should be borne in mind that in order to develop this most beautiful and complex apparatus, the co-ordinate development in due proportion of these beneficial obstructions and checks must have been simultaneously effected in order that their purpose should be duly served. In other words, to account for its formation by an indefinite series of minute happy accidents would seem to require such a successive occurrence of coincidences as to become an improbability so great as to be indistinguishable from impossibility.

St. George Mivart

THE "CHALLENGER" EXPEDITION

Bermuda

FROM the two visits made by the *Challenger* to Bermuda we learn a good deal about the vegetation of that island. Along the coast, which in some parts is irregular and rocky, and in others of a sandy nature, frequently with heaps of drifted sand, may be seen in abundance a species of *Borrichia*, a low shrub belonging to the compositeæ, *B. arborescens* D.C. being common in the West Indian Islands, and noted for having both glabrous and silvery leaves on the same plant, as well as the two forms on separate plants. In close proximity to the *Borrichia* was seen *Tournefortia gnaphalodes* R.Br., a Boragineous shrub from 2 to 6 feet high, with white flowers and downy leaves, and *Ipomœa pes-capræ* Sw. with its long stem, which frequently creeps to 100 feet or more, and its purple flowers. In the crevices of the rocks grow *Euphorbia glabrata* V., a shrubby glabrous plant common to the West Indies, and on the shores of Florida, Honduras, &c. A species of Tamarix is also abundant, as well as *Conocarpus erectus* L., and *Coccoloba uvifera* Jacq., known in the West Indies as the seaside grape, from the violet-coloured, pulpy acid-flavoured peiranth; an astringent extract like kino is likewise prepared from the bark, and the bark itself is used for tanning leather.

Many trailing plants scramble about on the sand dunes, assisting to bind the loose sand together. Amongst the most important of these is a hard, prickly grass, probably a species of *Cenchrus*, *Cakile æqualis* L.'Her, a singular cruciferous plant allied to our Sea Rocket, and a species of *Scævola*. The Mangrove (*Rhizophora mangle* L.) occurs in swamps similar to those which have been so often described by travellers; but beside the true mangrove swamps, there are others occupied by trees of *Avicennia*, *A. nitida* Jacq. being known in the West Indies as the black, or olive mangrove.

In the peat bogs, or marshes, which are surrounded by low ranges of hills, the most striking character of the vegetation is the ferns; species of *Osmunda* are abundant, as well as *Pteris aquilina* L. Some of the marshes, however, have their special character of fern vegetation some species, as for instance *Acrostichum aureum* L. (*Chrysodium vulgare* Fee), being found only in particular spots. The Junipers (*Juniperus bermudiana* Lun.) also thrive in the marshes, but none of the trees at present standing approach in size those that are occasionally found below the surface. These large trunks usually lie at a depth of about two feet. The average diameter of the trunks of existing trees may be taken at from two to three feet, and these are mostly unsound in the centre owing to the marshy ground in which they grow. The largest known living trees in the island measure respectively fifty-nine inches and thirty-nine inches in diameter; the first is hollow, but the second is apparently sound. Amongst other noticeable marsh plants are *Myrica cerifera* L., a shrub the berries of which, in Central America, yield wax from which candles are made, and *Rhus toxicodendron* L., the Poison Oak of North America.

In the fresh-water ponds or lakes inland, some of which are a quarter-mile long, and often are in close contiguity

to a peaty marsh, though the waters appear not to be affected by the peat but are said to be salt at certain periods, occur abundance of confervæ and minute algæ, as well as a species of *Ruppia*. In the shady damp hollows, at the entrances of the caves, is usually seen a rich growth of ferns, jessamine, and coffee trees of good size.

The general features of the indigenous vegetation of the islands are the Junipers, *Lantana camara* L., a verbenaceous shrub which grows in dense masses, and the Oleander, which also grows in abundance and is used for hedges. A few trees of the Date and Cocoa-nut palms may occasionally be seen, but their fruit produce is not sufficiently abundant to be of any importance. One of the greatest pests in the island in the form of a weed is *Leucæna glauca* Bth., which sends down its tap roots to a great depth, and is difficult to eradicate. It is a leguminous plant, and in its native state forms an ornamental tree.

The least cultivated part of the island is at Paynter's Vale, where orange and lemon-trees luxuriate in their wild state. From the prevailing dampness of the atmosphere all over the island, a species of Nostoc abounds not only in the caves and on the rocks near the seashore, but also amongst the roots of grass on lawns. Out of about 160 flowering plants collected in Bermuda *Morus rubra*, *Hibiscus arborea*, and *Chrysophyllum cainito* are the only three that do not occur in an absolutely wild state. Perhaps not more than 100 are true Bermuda plants. Many of the plants of the island were no doubt originally brought from the West Indies by the Gulf Stream, or the cyclones. The presence of American plants is perhaps to be traced more to the migrations of birds, which come in large numbers, more especially the American Golden Plover. Then, again, to account for the presence of other plants, there is the fact of the annual importation of large quantities of hay, and also of seeds, such as onion seed from Madeira and potato seed from America, with which other seeds are, no doubt, constantly introduced. Shipwrecks, also, which occur on the coast, are probably fruitful sources from whence new plants arise; as a proof of this, it is stated that a vessel with a cargo of grapes was recently wrecked and the boxes of grapes washed ashore, the seeds of which, being saved, were sown, and produced an abundance of young plants.

INDUSTRIAL CHEMISTRY

THE Society of Arts seems to be increasing its efficiency every year, "lengthening her cords and strengthening her stakes;" quite recently a Chemical Section has been added, which we believe will be productive of much practical benefit. At the opening of this Section on the 6th inst., the chairman, Dr. Odling, gave a valuable and interesting address, which, by the courtesy of the secretary of the Society, we are able to present to our readers :—

I have been desired by the Council to say a few words at this introductory meeting on the importance of Industrial Chemistry, but really to do so is to urge upon you a theme which requires no advocacy, I should think, on the part of anyone, and I am afraid it would be as tedious as thrice-told tales. If we look at the objects with which we are surrounded and consider how very few of them are in a state in which they are presented to us by nature, we shall find that the metamorphoses to which they have been subjected are essentially chemical ones; that is to say, wherever we find one kind of matter in nature, and somehow or other the matter is turned into another kind of matter, we submit it to a chemical change; and how very few indeed of the different kinds of matter with which we are surrounded are really in their primitive forms When we have mentioned wood and stone, I mean building stone, we have mentioned almost all. When we consider the gas which, though now gas, was a short time ago in the form of coal, or the glass of our windows which a short time back was in the form of sand, soda, and limestone, or if we look at the plaster of our rooms, which was originally limestone, which has undergone varied metamorphoses, and more particularly I might direct your attention to the metallurgical industries, especially iron, which was a short time before in the ironstone—all these are instances of the chemical metamorphosis to which we subject the different natural objects, and so change one kind of matter into another.

Among all these metamorphoses which are of a chemical nature there are some to which we more particularly apply the name of chemical manufactures. In reality, a brick is as much a product of chemical change; it was not originally the same matter it now is, but was produced by a change of chemical composition of its elements. But among these more particularly called chemical manufactures, the production of which is conducted in works which are called chemical works, are those performed in so-called alkali works; and I think I need have no hesitation in saying that these works have proceeded to a far greater development in this country than in any other, notwithstanding the fact that among the constituents received and metamorphosed by these works are many which are of foreign extraction, more particularly the pyrites, or other sources of sulphur, and the manganese or other sources indirectly of the chlorine manufactured at these works. And we see, that in the course of lectures which has been provided for us, three have reference especially to these manufactures, which are conducted exclusively at works which are denominated chemical works. We have a process for the manufacture of soda by Mr. Vincent; another on pyrites, as a source of sulphur, copper, and iron, by Dr. Wright; and another on the manufacture of chlorine, by Mr. Weldon.

Starting from the crude substances, coal and limestone, and pyrites and common salt, we have a production of soda which will be treated of more particularly in Mr. Vincent's address. Then we have the further manufacture of copper, sulphur, iron, and chlorine, which are the necessary economical concomitants. It is indeed remarkable, at the present day, how much the production of chemical manufactures takes in the working up of what were formerly waste products. Perhaps we could not have a more singular instance of this than in the utilisation to which that class of refuse, which was formerly known as burnt pyrites, is now put. Not only do we obtain from the original pyrites sulphur in a form which was formerly thrown away on a very large scale, but, moreover, copper and iron, which were also formerly thrown away in the burnt pyrites. And we have also one very remarkable product now obtained from pyrites on a comparatively large scale, and I may say, with regard to the manufacture of copper from pyrites, that the amount now produced—as Mr. Wright will tell you—from a material which was formerly thrown away, constitutes a very large proportion of the entire quantity now manufactured in the United Kingdom.

But in addition to that there is a very considerable manufacture of silver now going on also extracted from these waste pyrites. This extraction of silver from these pyrites, in which it occurs in an exceedingly minute proportion, has an essential interest for chemists in this point of view, that the processes which are adopted for its extraction really resemble most closely the processes which purely scientific chemists adopt in the laboratory. The pyrites are first of all heated with common salt, whereby the copper is converted into chloride of copper soluble in water, and the silver into the state of chloride of silver, which is soluble in the common salt solution; and not only so, but in this process of removing the soluble copper and the soluble silver from these pyrites,

the arsenic and the sulphur, which formerly prevented the burnt pyrites being put to any use, are got rid of, so that what remains is useful in a further stage of the iron manufacture. But with regard to the extraction of the silver, we find how important a knowledge of even delicate chemical processes is, in order to allow the extraction to be pursued with advantage. By the ingenious process of Mr. Claudet and Mr. Phillips, it is first of all examined by the nicest chemical means to see the exact amount of silver it contains, by a process rivalling in delicacy that which is pursued in laboratory research, and having ascertained exactly the quantity of silver contained in the solution, the exact quantity of extremely expensive reagent, iodide of potassium, which is required, is added to it to precipitate the amount of silver; and when the iodide of silver is thrown down the iodine is recovered to be used over and over again, and the silver itself is set free by means of metallic zinc, which forms iodide of zinc, thus setting free the silver. In this way, a considerable portion of silver is extracted.

I mention this as an illustration of the remarkably close association which is every day taking place between sure chemistry in the laboratory, and manufacturing chemistry in the factory. Now-a-days we have such out-of-the-way bodies, as they were formerly considered, as these different aniline products, as alizarine and chloral, which were formerly barely obvious in the laboratory, now made on a manufacturing scale. On the other hand, we find these different products of estimation, formerly confined to the laboratory, are now carried on in the manufactory, and thereby such an element as silver is produced by processes which are essentially laboratory processes. In this way it happens that we find many improvements in manufacturing chemistry are now produced by men who have obtained a reputation in other fields. For instance, I need scarcely refer to the names of Hoffmann, Perkin, and Nicholson, gentlemen known as scientific chemists and men of the highest eminence, before their attention was directed to manufacturing operations, and they realise on a manufacturing scale the results of their laboratory experience. In mentioning them, I ought not certainly to dissociate from them our lecturer this evening, Mr Field, who was so long and so highly esteemed in purely scientific circles for his admirable researches into a great number of compounds, more especially connected with mineral chemistry, before he devoted his great ability to the elucidation and improvement of the manufacture of aniline dyes, and subsequently to these metamorphoses of the bodies which we now use for illuminating purposes in the form of paraffine and ozokerit, and also the other candles which are composed of stearic acid, palmitic acid, and so on.

But while in this way manufactures derive a very great advantage from the light thrown on them by purely scientific chemists in one way or another, I do not think we ought to overlook the benefit which pure chemistry derives, on the other hand, from manufacturing operations. I do not mean the mere material gain that purely scientific chemists have enjoyed by the opportunity of examining minutely a great number of bodies, which previously it was almost impossible for them to obtain, but I think they have gained a very much greater knowledge of the especial subject of their studies — I mean chemical phenomena. We chemists take in our province every change by which one kind of matter becomes metamorphosed into another kind of matter, whereby that which was ironstone, for instance, becomes iron, whereby that which was sand, chalk, and soda becomes glass, and which takes place wherever one kind of matter is metamorphosed into another; but, after all, a great number of the metamorphoses which we must study take place in the test-tube and small vessels of similar character; and we are rather too apt, I say, to shut our eyes to those metamorphoses which take place on a large scale around us.

Those changes manifest themselves particularly in two forms. We have those by which the different forms of agricultural produce are furnished us by the vegetable kingdom, and by which they are metamorphosed into the animal kingdom. Here we have one great illustration of industrial chemistry—the chemistry by which crops are produced, and by which stock is fed and flesh is made. This feeding of stock and production of crops is one very large function of industrial chemistry, and I would venture to say that any scientific chemist who devotes his attention entirely to what takes place in the test-tube, and who neglects those changes which are constantly taking place around him, has a very imperfect notion of the subjects which he professes to investigate. And in addition to these changes thus taking place in natural processes, modified to a certain extent by art, we have three other processes which take place on a grand scale, by which from such substances as ironstone we produce metallic iron, from common salt, on the one hand, carbonate of soda, applied to the manufacture of glass and other useful purposes, and by which we provide also chlorine in its different combinations, applicable to so many purposes, more particularly in the preparation of our wearing apparel, and in our linen and fabrics of every description.

I think, then, that when we have the advantage of having these industrial subjects brought under our notice by men like our friend here, who are familiar, on the one hand, with the most recondite points of theoretical chemistry, and, on the other hand, with the greatest practical achievements which have been obtained in manufacturing chemistry, it will be of immense benefit to those who wish to study chemistry in its pure aspect, as they will see what can be done on a large scale, and what habitually is done, and what perseverance, assisted with chemical knowledge, has obtained for us. It must also be interesting to practical men, by throwing out suggestions capable of improvement in various branches of manufacturing art. I think, then, that the Society of Arts has really done a very useful work in bringing together men engaged in the purely scientific pursuit of chemistry on the one hand, and, on the other, men who are pursuing the application of the science with a view to the practical good of their kind. I do not know that I need trouble you with any further remarks, but I have attended here this evening with the greatest pleasure, because I feel how much advantage is likely to be derived by all classes of the community by the discussion of these problems which are so interesting to all, and I would venture to say as much in a purely scientific as in a practical point of view.

NOTES

SUFFICIENT attention has not been attracted to the fact that one of the recommendations of the Committee on Scientific Instruction has borne early fruit. Mr. Phillips Jodrell, desirous to promote research in physiology, has attached to the professorship of that science in University College, London, an endowment of 7,500*l.* to enable the professor to devote to biological investigation whatever time is not needed for the discharge of his duties as lecturer. This endowment is accompanied by the further sum of 500*l.*, to be expended in the purchase of the necessary apparatus. It is difficult to speak in terms sufficiently high of Mr. Phillips Jodrell's intelligent munificence, which, we have no doubt, will bear good fruit. It is gratifying that the recommendations of the Commission have so far had such an excellent result, and we only hope that Mr. Jodrell's handsome example will be largely followed by others who have enough and to spare.

OUR readers will no doubt learn with surprise and regret that M. Alglave, editor of the *Revue Scientifique*, and Professor of

Law in the faculty of Douai, has been suspended from his professorial duties for one month, and has received notice that he must either resign his position as professor or give up the editorship of the *Revue Scientifique*. The reason for this vexatious proceeding we have not learned; but to outsiders it must seem a wanton and mischievous exercise of authority, although the fearless way in which the *Revue* states scientific facts and conclusions may have something to do with it. The *Revue Scientifique* holds the first rank among French scientific journals, contains from week to week the cream of scientific work both French and foreign, and any interference with its efficiency would be a great blow to the cause of Science in a country where a knowledge of the methods and solid results of Science is much needed. If the threat with which M. Alglave is menaced be carried out, those who thus abuse their little brief authority will be despised by the whole educated world. We read in the *Progrès du Nord* that M. Terrat has been appointed to take M. Alglave's place, and that when the former entered the class-room the students retired silently and in perfect order, leaving M. Terrat to lecture to the walls of the amphitheatre and two members of the *Cercle Catholique* who did not deem it prudent to join in the protest of their class-fellows; the students, we believe, have presented to their professor a unanimous address of sympathy. Let us hope that before the expiry of the month those who are responsible for this treatment of M. Alglave will think better of it, and restore the professor to the position he appears to have filled so well, permitting him at the same time to retain charge of the journal which is among the things that reflect the highest credit on France.

THE Chimpanzee, which during the last two and three-quarter years has been an endless source of instruction and amusement to visitors at the Zoological Gardens, after an illness of two months' duration, died on Friday last. The post-mortem examination showed that the cause of death was acute tuberculosis of the peritoniteum, almost exclusively confined to the serous membrane covering the liver and spleen, the omentum and small intestine being slightly affected. A large bronchial gland was on the verge of suppuration, but the lungs were healthy. There were no symptoms of hectic during life, and much subcutaneous and omental fat were found after death.

THE French Meteorological Society has resolved to hold an extraordinary *réunion* during Easter-week, a time when a considerable number of French and foreign meteorologists are in Paris. This meeting has for its object to strengthen the relations which exist between the Society and provincial observers, and to study in common questions of general interest in meteorology.

THE Meteorological Office has resolved, in compliance with the wish of the majority of subscribers to the lithographed sheets of hourly readings from their observatories, which are about to appear, to issue the sheets in monthly, not quarterly parts.

IN addition to the *Bulletin Météorologique du Nord*, of which we lately announced the publication, we are glad to learn that Capt. Hoffmeyer, the Director of the Meteorological Institute of Denmark, has commenced the issue of a daily lithographed chart, for his own country, Norway, Sweden, and North-west Russia. He has also published an explanation of the chart for the use of subscribers. This chart is most valuable, as it supplements our own daily weather charts and those of the *Bulletin International*, for a district whence accurate information is seldom obtainable by telegraph in Western Europe.

IN a recent number we intimated that the Perthshire Society of Natural Science had interrogated the Parliamentary candidates for the county and city of Perth as to their opinions on the questions of State help to Science, a responsible Minister of Education, and the promotion of Scientific Exploring expeditions. Answers—favourable, we are glad to say—were returned at the time only by the two Conservative candidates, one of whom, Sir W. Stirling Maxwell, is now M.P. for Perthshire. We are now glad to give place to the somewhat tardy reply, addressed to the secretary, of the Hon. Arthur Kinnaird, Member for the City of Perth:—"1, Pall Mall East, 18th Feb. 1874.—Dear Sir,—I was surprised to find copied into a London paper from a Scotch journal the questions put in your letter of the 29th January last, with the statement that they had not been answered by me. The fact of my being, as I believe I am, one of the patrons of the Perthshire Society of Natural Science should have been, it appears to me, a sufficient guarantee of my approval of the objects of your institution; and my active co-operation with Capt. Wells in his efforts during the last session of Parliament to obtain the sanction of Government to a proposed grant for the furtherance of Arctic exploration, further approves my appreciation of the objects you advocate, in my willingness to support State expenditure for well-devised schemes of scientific research and educational purposes.—Yours truly, A. Kinnaird."

H. N. MARTIN, B.A., Cantab, D.Sc. Lond., has been appointed Lecturer on Physiology at Christ's College, Cambridge. Dr. Martin obtained an open scholarship for Natural Science at Christ's College, and graduated in the Natural Sciences Tripos, obtaining the first place. Lately he has acted as assistant to Dr. Michael Foster in the Physiological Laboratory of the University. A paper by Dr. Martin on the "Structure of the Olfactory Mucous Membrane" appeared in the last number of the *Journal of Anatomy*, and was reprinted in the Studies from the Physiological Laboratory of the University, Cambridge, edited by Dr. Michael Foster.

THERE will be offered, at the Matriculation exhibition at New College, Oxford, beginning on Wednesday, May 21, at 9 A.M., two Exhibitions, tenable for three years, of the annual value of 50*l*. each. These Exhibitions are open to all persons who have not already been matriculated at another College. In the election to one of the Exhibitions a preference will be given to proficiency in Natural Science, if there is any candidate of sufficient merit in the judgment of the examiners. Further account of the examination will be supplied on application to the Warden.

THE Science and Art Department has published a catalogue of apparatus for teaching chemistry, containing 112 items, with prices from which a deduction of 50 per cent. is given. We should advise all our readers who are interested in the subject to obtain the catalogue. The same Department has also formed a collection of travelling apparatus for illustrating instruction in Physical Geography, which will be lent, for a short time, to teachers of the subject referred to. The apparatus consists of a set of physical maps of the world and the various continents, by Prof. Sydow, models of Mount Vesuvius, of Mont Blanc, and of the Thames Valley.

WE regret to record the death of Dr. Forbes Winslow, which took place at Brighton on the 3rd instant, at the age of 63 years.

WE formerly announced the proposal for an international memorial to Captain Maury, which is to take the shape of a Lighthouse on the Rocos, to the importance of which Maury called attention in his "Sailing Directions." We learn from *Ocean Highways* that the President of the Board of Visitors of the Virginian Military Institute addressed a letter to the Governor of Virginia on Jauuary 23, requesting him to lay the question of the Maury memorial before the General Assembly, for such moral support as may fitly be given by the representatives of a State which gave Maury to the world. A joint committee of members of the Senate and House of Delegates has since been appointed; and the hearty co-operation of the Govern-

ments and Scientific Societies in Europe is confidently expected; for Maury's services have benefited not his own country only, but the maritime interests of the whole world.

ON the 19th of February, Dr. Peters, of Hamilton College, New York, discovered a planet in $11^h\ 19^m$ right ascension, plus 4 deg. 25^m declinatlon.

M. CHARLES SAINTE CLAIRE DEVILLE, the meteorologist, announced publicly before the French Institute, that the week from March 9 to 16 would be a very cold one. The prognostication is in a fair way of being fulfilled.

THE last scientific letter written by the lamented M. Quetelet was to General Myer, the Director of the American Meteorological Service. Its purpose was to inaugurate the daily intercommunication of meteorological news between the States and Belgium. The scheme so originated is working regularly and was not interfered with by the death of the learned and respected Belgian astronomer.

THE *Lancet* says that the authorities of the University of Aberdeen have now under consideration a proposal to institute a new degree in arts—that cf Bachelor of Science.

HERR VON DEM BORNE writes to the *Deutsche Fisherei Verein*, in Berlin, that he is at present occupied upon an exhaustive treatise, on the most recent and best methods and implements of fishing with the hook and line, especially as used in England and North America, and is desirous of receiving information on these subjects from dealers and others, to be embodied in his proposed work.

VELOCIPEDES are becoming an institution in Paris for forwarding messages from the Exchange (Bourse) to the central telegraphic office, rue de Grenelle. The rates charged by "velocemen" are two shillings. The run there and back, including delivery of messages, takes about 25 minutes for a distance of 3 miles 1,320 yards. It is contemplated by some speculators to establish a public company. When Marshal Bazaine's trial was going on, velocipedes were used for conveying messages from Versailles for the *Moniteur*, one of the Parisian papers. The single run was charged a pound sterling, and was accomplished in 45 minutes for a distance of 12½ miles, at a quicker rate than the railway trains. But the road descends all the way, Versailles being on a higher level than Paris, and the railway is circuitous; stoppages are also very frequent on the line.

CARRIER-PIGEONS are largely used by Parisian periodicals for carrying latest intelligence. They start from Versailles from two o'clock in the afternoon till three. The average number is thirty pairs, and the charge four shillings each pair. The journey is accomplished in twelve minutes when fogs are not frequent. It is not legal for newspaper editors to hire a wire for their private use.

M. HENRY GIFFARD, the inventor of the *Injecteur*, has constructed a railway carriage with a patent suspension of his invention, which prevents the passengers from feeling any inconvenience from oscillation. The first public experiments will be on the Versailles railway, just after the impending parliamentary holidays.

THE election of a successor to the late Dr. Nelaton has given rise to a severe contest in the Secret Committee of the French Academy of Sciences; for more than a month it has obstructed the usual routine of the Academy. The reports for yearly prizes, which are ready for adoption, were not read over. The number of competitors is greater than usual, amounting to seven.

THE Parisian Municipal Corporation has decided upon the building of a large bridge on the Seine, which in point of length will be equal to Blackfriars or Waterloo Bridge, London; but instead of being placed at right angles to the current, it will be placed in an oblique direction. This extraordinary step is taken to connect the rue des Etats on the left bank with the old arsenal quarter on the right bank.

M. FIGUIER has issued through Hachette his *Année Scientifique*. It is the 17th volume of the whole series.

AN International Agricultural Exhibition is to be held on a grand scale at Bremen, under the patronage of the Crown Prince of Germany, from June 13—21 next. The North German Lloyd will grant special facilities to the English exhibitors for the conveyance of implements from London, Southampton, and Hull.

THE enormous extent of the destruction of buffaloes on the Western plains of the United States seems to have undergone no diminution during the present winter, and there is every reason to fear that, should this continue a few years longer, the animal will become as scarce as is its European congener at the present day. At present, thousands of buffaloes are slaughtered, every day, for their hides alone, which, however, have glutted the market to such an extent that, whereas, a few years ago, they were worth three dollars apiece at the railroad stations, skins of bulls now bring but one dollar, and those of cows and calves sixty and forty cents, respectively. A recent short surveying expedition in Kansas led to the discovery of the fact that, on the south fork of the Republican, upon one spot, were to be counted six thousand five hundred carcases of buffaloes, from which the hides only had been stripped. The meat was not touched, but left to rot on the plains. At a short distance hundreds more of carcases were discovered, and, in fact, the whole plains were dotted with putrefying remains of buffaloes. It was estimated that there were at least two thousand hunters encamped along the plains, hunting the buffalo. One party of sixteen stated that they had killed twenty-eight hundred during the past summer, the hides only being utilised.

A COPY of the Calender for 1873-4, of the Imperial College of Engineering, Tokei, Japan, has been forwarded us. The course of study prescribed, both general and special, theoretical and practical, and the regulations for the government of the College, appear to us to be all that at present could be desired.

WE are asked to state that the Annual Dinner of the members of the Institution of Civil Engineers has been appointed to take place at Willis's Rooms, St. James's, on Saturday, March 21. Mr. T. E. Harrison, the president, will occupy the chair.

WE are glad to see that Guido Cora's well-conducted Italian geographical journal, *Cosmos*, is to be henceforth issued monthly, instead of every two months.

AN aëronautical society of Paris, the "Aërial Sport," has published a programme of an aërial spring meeting to be held in the neighbourhood of Paris, very likely Vesinet. The object is to send in the air small fire balloons carrying *des mèches illumées*, whose length has been calculated so that the cargo of the balloon may fall close to a post chosen. Every champion is to choose his own wind; but nobody has a right to approach closer to the post than three miles. It is a kind of drill for shelling a place with balloons by taking advantage of the wind.

THE additions to the Zoological Society's Gardens during the last week include a Javan Rhinoceros (*Rhinoceros sondaicus*) from Java, purchased; a Negro Tamarin (*Midas ursulus*) from North Brazil, presented by Mr. W. Thomson; two Goshawks (*Astur palumbarius*), European, one presented and the other deposited by Mr. G. Lascelles; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. S. Waight; two Verreaux, Guinea Fowl (*Numida eduardi*) from East Africa; two Crowned Pigeons (*Goura coronata*) from New Guinea, and a Common Cassowary (*Casuarius galeatus*) from Ceram, purchased.

SCIENTIFIC SERIALS

Ocean Highways, March.—The following are the original articles in this number:—"Dr. Livingstone and the Cameron Relief Expedition;" "Francis Garnier—In Memoriam," a highly and deservedly eulogistic memoir (by Colonel Yule, C.B.) of this brave and high-minded soldier and explorer, whose untimely death we recently noticed; "Bhawalpur;" "An Account of the Early Jesuit Missions in the La Plata," by A. A. Geary; and "The British India Steam Navigation Company."

THE *Geological Magazine*, March.—The following are the original articles in this number:—"The Leinster Coal-field," by J. M'C. Meadows (with a page map); "On a new Species of *Dithyrocaris* from the Carboniferous Limestone, &c.," by Henry Woodward, F.R.S., and Robert Etheridge, jun. (with a plate); "Glacialoid or Rearranged Glacial Drift," by G. H. Kinahan; "On some new Devonian Fossils," by Prof. H. Alleyne Nicholson (with a woodcut and plate); "Reply to Mr. Poulett-Scrope," by Robert Mallet, F.R.S.

Quarterly Journal of the Meteorological Society, January.—This number contains the following papers:—"Notes on Meteorology of Vancouver Island," by R. H. Scott, F.R.S.; "The Thunderstorm at Brighton on October 8, 1873, and its effects," by F. E. Sawyer; "Some of the Considerations suggested by the Depressions which passed over the British Islands during September 1873," by F. Gaster; "On an improved form of Aneroid for determining Heights, with a means of adjusting the Altitude Scale for various Temperatures," by Rogers Field; "On the Hurricane of August 1873, which moved in a curved track round Bermuda between the 20th and 23rd, and passed on to Nova Scotia and Cape Breton on the 24th, doing extreme damage both at sea and on land," by Capt. H. Toynbee (with a plate); "On a Mercurial Barometer for the use of Travellers, filled by the spiral cord method," by Staff-Commander C. George, R.N.; also an account of the discussion on the best form of Thermometer Stand, which took place at the meeting of November 19, 1873.

Archives des Sciences Physiques et Naturelles, Jan. 15, 1874.—The principal article in this number is an exhaustive study, by Prof. Forel, of the *seiches*, or peculiar tidal phenomena, which have long been observed on the lake of Geneva. The subject is treated in five sections, as follows: the seiches at Geneva and at Morges compared; oscillatory movement in the harbour at Morges, analogous to seiches; the movement of oscillation of seiches; experimental study (with special apparatus) of the laws of oscillation of libration; and lastly, comparisons and conclusions. Prof. Forel adheres to the theory generally accepted in explanation of the phenomenon, viz., that it is due to variations of atmospheric pressure; the pressure diminishing at one part and increasing at another, the surface of the water rises in the former case and sinks in the latter. Thus a swinging undulation is produced. Some of the larger seiches are attributed to earthquakes. The amplitude differs in different seiches; and in the same seiche it varies from one point of the lake to another. The duration of different seiches also varies in the same locality; and the duration of seiches is longer at Geneva than at Morges. These and other effects the author seeks to explain, harmonising them with physical phenomena studied in his apparatus.—In a note on the surface of waves, by M. Charles Cellerier, it is sought to show that there is no real disagreement between the laws of double refraction, as furnished by observation, and the theory based on molecular movements. It is probable, he thinks, that the ordinary ray, whether in uniaxial crystals, or in principal sections of crystals with two axes, has not quite the direction generally assigned to it; though the deviation, without disagreeing with theory, may be so small as to escape observation.—In the department of zoology, we may notice a review of recent researches by Haeckel, Bütschli, and others, on Infusoria.

Memorie della Soc. degli Spectroscopisti Italiani, September, 1873.—Prof. Tacchini contributes a paper on his observaions on the magnesium lines and 1,474 line seen bright on the sun's limb, from which it appears that the 1,474 line is always visible in a magnesium region; and further, that it frequently appears by itself where no magnesium is seen. Two beautifully-executed chromolithographs of the chromosphere on the 15th and 16th of July last accompany the paper, showing the relative intensities of the magnesium and 1,474 lines, together with their positions. The intensity of the magnesium lines seems the greater of the two, though not covering so extensive a region.—Father Secchi gives a note on the spectrum of iron, and other metals, obtained by volatilisation with fifty Bunsen's cells. He appears to find that the 1,474 line is not due to iron, and that different kinds of iron give slightly different spectra. He also gives a drawing of the carbon spectrum from the electric light, which appears similar to that of cyanogen, with the addition of five equidistant bands in the yellow and red.—The tables of Mr. E. Loomis, containing the maximum years of sun-spots, the maximum years of magnetic declination, and the maximum years of auroral display from 1778 to 1870, are given, from which, at a glance, it is seen that the maxima of all three occur in the same years with very small exceptions, and the years of minima correspond even better.

Justus Liebig's Annalen der Chemie u. Pharmacie, Band 170, Heft 3. This number contains the following papers:—"Communications from the Chemical Laboratory of the Polytechnic School at Delft: iv. Researches upon Podocarpic Acid," by A. C. Oudemans, jun. This acid is obtained from the resin of *Podocarpus cupressina var. imbricata* Blume.; a tree growing in Java. The formula assigned to the acid is $C_6H_2\left\{\begin{array}{l}OH\\COOH\\CH_3\\C_9H_{15}\end{array}\right.$ $= C_{17}H_{22}O_3$. Some of the salts are described, and also the mono- and di-nitro substitution products. A sulpho-acid, amidated, and brominated derivatives have been obtained, likewise an acetyl derivative. The author has studied exhaustively the decomposition products of the new acid, and these have led him to the constitutional formula above given.—Upon Cymene, by F. Beilstein u. A. Kupffer. The authors have examined cymenes from cumin-oil and from camphor, and find them to be identical. The same authors contribute a paper on oil of wormwood. This oil yields by distillation a terpene, absinthol ($C_{10}H_{16}O$), and a deep blue oil.—"Crystallographic researches on the calcium salts of cymene-hyphersulphonic acid," by M. Jerofejew.—"Cumic acid," by F. Beilstein u. A. Kupffer. The authors obtain the potassium salt of this acid by acting on cumin-oil with fused potash.—A lengthy paper on the salts of ethylaldehyde-sulphurous acid and the action of the sodium-sulphites upon ethylidene chloride, by Hans Bunte.—On the formula of silicates, by Prof. V. Wartha.—The concluding paper is by Otto Sigel, on the constituents of arnica water and of the essential oil of arnica.

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, March 5.—Special General Meeting, G. Busk F.R.S., vice-president, in the chair. After the chairman had, in a short conciliatory address, stated the reasons which had induced the Council to summon the present meeting, he called on Mr. W. Carruthers, F.R.S., who moved "That a Committee be appointed to consider the Bye-laws and to suggest to the Council such alterations, omissions, or additions as they may think desirable." The motion having been seconded by Mr. W. S. Dallas, Major-General Strachey, F.R.S., moved as an amendment, which was seconded by Mr. C. J. Preese, "That, inasmuch as it appears that there are differences of opinion in the Society as to the legality of the alterations of the Bye-laws made at the meeting of January 15 last:—(1) This meeting, retaining complete confidence in the President and Council of the Society, requests them to obtain the opinion of some legal authority, whether these alterations are legally binding on the Society or not; (2) That if the opinion be that the said alterations are legally binding, no further steps be taken in reference to them; (3) That if the opinion be that the said alterations, or any of them, are not legally binding, the Council be requested to take the necessary proceedings for setting aside the vote of January 15."—A second amendment was moved by Mr. J. E. Harting;—"That the case having been already submitted to Council, the opinion thereon be read for the information of the meeting." After much discussion, in which Sir John Lubbock, Dr. Thos. Thomson, Dr. Trimen, Prof. Thiselton-Dyer, Mr. H. G. Seeley, and others took part, Mr. Harting's amendment was withdrawn, and the vote taken on Major-General Strachey's amendment, which was carried, and was afterwards adopted as a substantive resolution.—Sir John Lubbock, Bart, F.R.S. then moved and Mr. W. Carruthers, F.R.S. seconded a resolution expressive of the high sense entertained by the meeting of the eminent services both to

the Society and to Science rendered by the President during his long tenure of the chair, which was carried unanimously by acclamation; and the meeting closed with a vote of thanks to the chairman.

Zoological Society, March 3.—Dr. E. Hamilton, vice-president, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of February, 1874, and called especial attention to a Malayan Hornbill (*Buceros malayanus*) new to the Society's collection, acquired by purchase; a Python, presented by Mr. C. J. Noble, of Hong Kong, having been captured in his garden on the Chinese mainland; and a young male of an undescribed species of Deer from Northern China.—A letter was read from Sir Henry Barkly, K.C.B., Governor of the Cape Colony, announcing that he had obtained a pair of young Eared Seals (*Otaria pusilla*) for the Society's collection.—A communication was read from Mr. W. H. Hudson, of Buenos Ayres, describing the parasitical habits of the three species of *Molothrus* found in Buenos Ayres, namely, *M. bonariensis*, *M. badius*, and *M. rufo-axillaris*.—Mr. Sclater read an account of a small collection of Birds obtained by Sir Graham Briggs in the island of Barbados, West Indies.—A second paper by Mr. Sclater contained the description of an apparently new form of the family *Icteridæ*, which he proposed to call *Centropsar mirus*.—A communication was read from Dr. J. E. Gray, F.R.S., containing some remarks on *Crocodilus johnsonii* Krefft, from Northern Australia, of which he proposed to form a new genus, *Phylas*.—Mr. W. Saville Kent, F.L.S., read a paper on a huge Cephalopod or Cuttle Fish, announced by the Rev. M. Harvey as lately encountered in Conception Bay, Newfoundland, and of which a tentacle 16 feet long has been secured for the St. John's Museum (NATURE, vol. ix. p. 332). Mr. Saville Kent contributed the additional evidence of an arm 9 feet long preserved in the British Museum, in proof of the gigantic dimensions occasionally attained by certain members of this order of the Mollusca, and proposed to institute the new generic title of *Megaloteuthis* for their especial reception; he further suggested distinguishing the Newfoundland example as *Megaloteuthis harveyi*, in recognition of the service to science rendered by Mr. Harvey, in his record of and steps taken to preserve so valuable a trophy.

Geological Society, Feb. 25.—John Evans, F.R.S., president, in the chair. The following communications were read:—Geological Notes on a Journey from Algiers to the Sahara, by George Maw. The author commences by describing the details observed on his journey from Algiers to L'Aghouat, on the borders of the Sahara. The distance traversed was 285 miles, or about 210 miles in a straight line, and in a direction nearly north and south. No eruptive rocks were observed. The oldest rock is a boss of mica-schist and gneiss behind the city of Algiers; it forms a low anticlinal, with a north and south strike. The pass through the gorge of the Chiffa in the Lesser Atlas shows hard slaty rocks dipping south at a high angle; they are repeated as an anticlinal on the south side of the higher part of the Tell plateau, and are probably Mesozoic. In the plain separating the Tell from the Hauts Plateaux, and on the south side of the latter, red and yellow sandstones form anticlinals; these rocks resemble the Bunter in mineral characters, and are overlain by red marls resembling the Keuper. In the northern escarpment of the Hauts Plateaux saliferous marls are exposed, interstratified between the sandstones and below the red and grey marls. Crystals of salt and gypsum are intimately mixed with the grey marls, and the so-called "Rochers de Sel" are capped with great blocks of rock tumbled about in confusion, the position of which the author ascribes to the failure of support due to the solution of the salt in the underlying salt-marls. A thin series of bright red and green marls is seen to overlie the red sandstones in several places; and above this is an immense series of dark grey marls, interstratified with argillaceo-calcareous bands, forming a great synclinal of the Hauts Plateaux, and a contorted mass on the Tell plateau. These are probably cretaceous. At L'Aghouat they are overlain by fossiliferous beds, probably of Miocene age. Other Tertiary beds observed are soft yellow calcareous freestones on the flanks of the promontory of Algiers and of the Lesser Atlas, and some red and grey marls and ferruginous freestone capping the Tell plateau, the former at a height of 100–900 feet, and the latter of 2,500–4,000 feet above the sea-level. The plain of the Mitidja, between the Lesser Atlas and Algiers, consists of grey loam with shingle-beds, of post-tertiary age. A similar loam covers the great plain of the northern Sahara, and rises to a height of 2,700 feet. Raised beaches occur on the coast up to an elevation of 600 feet above the sea-level; and similar beaches are found inland, south of the Tell plateau, at a height of 2,000 feet. The oldest land in the line of section is the anticlinal of mica-schist near Algiers, the strike of which is nearly at right angles to that of the other rocks. The upheaval of the Mesozoic rocks was contemporaneous with the first upheaval of the Lesser Atlas; it was followed by a long period of denudation, and this by a subsidence of at least 3,000 feet in Tertiary times, during which the Miocene deposits were formed. The Tell plateau was thus elevated at least 4,000 feet, and the district north of the Lesser Atlas at least 1,000 feet, the north face of those mountains probably marking a post-tertiary line of fault of 3,000 feet. This operation was followed by a long period of denudation, and this by a post-tertiary depression, which the author terms the "Sahara Submergence," after which the land was re-elevated at least 3,000 feet, but perhaps considerably more. A gradual subsidence appears to be still taking place.—On the Trimerellidæ, a Palæozoic family of the Palliobranchs or Brachiopoda, by Thomas Davidson, F.R.S., and Prof. William King. In this memoir the authors describe in detail certain Brachiopoda, for which they propose to establish a distinct family, discuss the characters and affinities of the family, and indicate certain geological considerations which arise from their study of its numbers.—Note on the occurrence of sapphires and rubies *in situ* with Corundum, at the Culsagee Corundum Mines, Macon Co., North Carolina, by Col. C. W. Jenks. Communicated by David Forbes, F.R.S.

Chemical Society, March 5.—G. C. Foster in the chair.—A paper on the spontaneous combustion of charcoal, by Mr. A. F. Hargreaves, in which he pointed out the best wood for charcoal for the manufacture of gunpowder, and also the best method of charring it. It appears that if it is ground too soon after being burnt the charcoal is liable to take fire spontaneously.—The other communications were—Researches on the action of the copper-zinc couple on organic bodies: Part V. On the bromides of the olefines: Part VI. On ethyl bromide, by Dr. J. H. Gladstone and Mr. A. Tribe.—Researches on the preparation of organo-metallic bodies of the C_nH_{2n} series of hydrocarbons, by Dr. D. Tommasi.—Note on the action of trichloracetyl chloride on urea, by Messrs. R. Meldola and D. Tommasi; and the agglomeration of finely-divided metals by hydrogen, by Mr. A. Tribe.

Royal Microscopical Society, March 4.—Chas. Brooke, F.R.S., president, in the chair.—A paper was read by Mr. Alfred Sanders, entitled "A Contribution towards a Knowledge of the Appendicularia," in which he minutely described specimens found at Torquay and Weymouth, and illustrated the subject by diagrams. A short discussion ensued as to the best methods of observing and preserving these delicate organisms.—Two papers by Dr. Royston Pigott were afterwards read by the secretary, the first "On the Verification of Structure by means of Compressed Fluid," the second being entitled "A Note on the President's remarks on Dr. Pigott's Aplanatic Searcher."—Dr. Pigott subsequently gave an extended explanation of the contents of his papers, and also detailed a new method of determining the refractive index of covering glass.

Entomological Society, March 2.—Sir Sidney S. Saunders, president, in the chair.—Mr. M'Lachlan exhibited two male examples of an Orthopterous insect belonging to the family *Locustidæ*. They were said to be sold in the streets of Shanghai, confined in ornamental wicker cages, and bought for the sound they produced. The species appeared to be undescribed, and to pertain to a new genus allied to *Xiphidium*. Mr. M'Lachlan also exhibited a series of examples illustrating the natural history of *Oniscigaster wakefieldi*, from New Zealand, described and figured by him from the female imago in the *Entomologist's Magazine* for October 1873. The series now exhibited comprised the male imago, female sub-imago, adult nymph, and larva. The lateral wing-like horny expansions of the terminal segments of the abdomen in the imago and sub-imago are continued in the aquatic conditions on each segment of the abdomen, and in addition there are similar formations along the back of the abdomen, placed longitudinally and vertically. The adult nymph appears to possess no external gills or laminæ, but they are conspicuous in the less mature larva on each side of the ventral surface of the abdomen.—The Rev. A. E. Eaton exhibited some Arctic insects which he had brought from Spitzbergen; and also some excellent photographs illustrating the scenery of the country.—A further communication was received from Mr. Gooch

respecting the injury to the coffee-trees in Natal from the Longicorn beetle, *Anthores leuconotus* Pascoe.—Papers were communicated, "On some new Species of South African *Lycænidæ*," by Mr. Roland Trimen, and "Descriptions of new Species of *Lycænidæ*," from his own collection, by Mr. W. C. Hewitson.

Society of Biblical Archæology, March 3.—Dr. Birch, F.S.A., president, in the chair.—The following papers were read:—Translation of an Egyptian fabulous romance, "The Tale of the Doomed Prince," from the Harris Papyri, by C. W. Goodwin. The translator drew attention to the peculiar features of this ancient story, resembling in so many points the romances of the mediæval period, which may have had a common origin.—Translation of an historical narrative belonging to the reign of Thothmes III., by C. W. Goodwin.—Observations upon the Assyrian verbs *Basu* and *Qabah*, by Prof. William Wright. This paper consisted of a critical analysis of the roots of the above verbs, and their cognate analogues in other Semitic languages.

Geologists' Association, Feb. 6.—Henry Woodward, F.R.S., president, in the chair.—On the probability of finding Coal in the Eastern Counties, by John Gunn, F.G.S. Mr. Gunn gave the preference to a boring on the south of Essex, and proceeded to state the grounds on which he recommended another boring at Hunstanton, or along the outcrop of the Kimmeridge clay, in Norfolk. He detailed the several papers which he had read at the meetings of the British Association at Nottingham, Brighton, and Bradford, in proof of the existence of a forest bed in Norfolk and Suffolk, which he called the Anglo-Belgian basin, of a succession of growth of forests, and of alternate elevations and depressions which have taken place in that region, and argued thence, by analogy, the extreme probability that such existed in the carboniferous epoch. Mr. Gunn represented that if the southerly dip of the Harwich slaty rocks extended in a northerly direction it must have been reached at the Norwich boring, which was sunk considerably lower than that at Harwich, and did not pierce through the gault. Mr. Gunn dwelt especially upon this as the most serious objection to the prospect of reaching coal at Hunstanton, or rather carboniferous beds, expressed so strongly by Prof. Hall at the Brit. Ass. meeting at Brighton. Mr. Gunn also referred to the evidence of local subterranean movements in proof of the proximity of disturbances acting upon what he regarded as a thin envelope of tertiary or secondary deposits probably not exceeding 1,000 feet, and perhaps much less. He referred to the evidence of boulders, which he hoped to adduce on a future occasion.—On the Geology of Nottingham, by the Rev. A. Irving, F.G.S. Part 1.

Edinburgh

Geological Society, Feb. 26.—David Milne Home, F.G.S., vice-president, in the chair.—The following papers were read:—Notice of large striated boulder in Tynecastle Sandpit, a quarter of a mile west of Dalry Cemetery, Edinburgh, by D. Milne Home.—On glacial phenomena in the neighbourhood of Edinburgh—(1) the Pentland Hills; (2) Bruntsfield Links; (3) Blackford Hill; (4) Tynecastle—by D. J. Brown.—Notice of a section in the building excavations at Tynecastle, by Ralph Richardson.—On glacial phenomena in the Pentland Hills and neighbourhood of Edinburgh, by John Henderson.—Mr. Milne Home's paper, which was illustrated by diagrams, described the boulder as being well rounded on the sides, and its greatest length as 4½ ft., its greatest width 4 ft., its thickness about 2 ft. Its upper and under surfaces were distinctly grooved, and most deeply in the line of the longer axis, which lay N.E. by E. There were some fainter striæ oblique to that line. From a comparison of the striations, he concluded that the superior and lateral striæ had been made after the stone was laid in the bed where found. The stone, which was of greenstone, lay on a bed of compact muddy sand, containing stones which were mostly angular. Above the stone was a considerable deposit of sand, and over that a series of gravels with clayey and sandy beds, all stratified, above which was the soil—the whole deposit being a bank from 20 to 30 ft. thick. This great bed of sand and gravel, in the upper part and west side of which the boulder was found, had been originally a submarine bank. Its height above the present sea-level was about 200 ft. How much above this level the sea stood when this bank was formed was, of course, only matter of conjecture. The nearest rocks similar to the boulders were situated to the westward; most probably, therefore, it had been rafted on ice from that quarter; and, by reason of the ice stranding on this sandbank, the boulder had been deposited there. The deep striæ on the under side showed that the boulder after being deposited on the sea bottom, had been pushed forward easterly. After it had stuck fast it had been striated on the top and exposed sides, by hard and sharp rocks pushed over it, probably by icebergs. The under striæ evidently indicated that they were begun to be formed from the east side, whilst the upper striæ indicated that they had been begun to be formed by some agent passing over from the westward by the pressure of floating ice. Mr. Milne Home stated that a boulder had been recently found on Sir Thomas Hepburn's property in East Lothian which also bore evidence of having been at one time subject to the action of floating ice.

Paris

Academy of Sciences, March 2.—M. Bertrand in the chair.—The following communications were read:—On the proper nature of the principle of correspondence, by M. Chasles.—On the descending motion of solar and terrestrial cyclones, and on the formation of their opaque envelopes, by M. Faye. This is a reply to a paper by Dr. Reye, and is a defence of the cyclone theory of sun-spots.—On the acid waters which rise in the volcanoes of the Cordilleras, by M. Boussingault. The author considers the simultaneous occurrence of chlorides and sulphates in the igneous rocks the cause of the formation of hydrochloric, sulphurous and sulphuric acids in volcanic emanations, thermal waters, &c.—Meteorology of the month of January 1874 at Tougourt, by M. Ch. Sainte-Claire Deville.—Observations on solar prominences during the last quarter of the year 1873. Results furnished by the employment of diffraction gratings instead of prisms in the spectroscopic observation of the prominences, by P. A. Secchi. The author has observed the coincidence of spots with eruptions on the sun's limb on eighty-nine occasions. Eight times only were spots seen without an eruption. A remarkable case is recorded of the outburst of an eruption during the course of an observation.—On the reduction of bilinear forms, by M. G. Jordan.—On the refraction of gases, by M. Mascart.—Organogenesis compared with androgenesis in its relations to natural affinities (*class Personatæ*), by M. Ad. Chatin.—New species of the genus Dipterocarpus, by M. J. Vesque. THE CHEMICAL SOCIETY'S JOURNAL

THE man who jokingly said that he had to give up the study of chemistry when the science became so bulky that its Handbook required a wheelbarrow for its conveyance, expressed a truth which has been painfully felt by many scientific workers. With continual fresh additions to our knowledge, anything like a comprehensive grasp of a large science must become daily more and more difficult; but while this difficulty is generally felt, it occurs with special force in the science of chemistry. Chemistry, of all sciences, has perhaps the most unlimited capacity for development. Its subject is enormous, including the whole of nature, animate as well as inanimate. Nor is the chemist satisfied with studying the properties of matter as they are exhibited in the natural operations of the world around us, even this wide and attractive field of observation does not content him; he has made the grand discovery that the elements are his servants; that he can at will take to pieces in his laboratory the compounds found in nature, and construct therefrom a multitude of new bodies. Chemistry may thus be said to produce the matter upon which it feeds; the extent to which the production of new compounds can be carried seems practically unlimited, and these become, in most cases, the starting points of fresh investigations. We have here the principal cause of the wonderful development of modern chemistry; armed with such power, it cannot but abound in valuable discoveries, and furnish, at all times, copious results. As a consequence of this rapid development of the science, it has become a matter of the greatest difficulty for the investigator, the teacher, or the manufacturer, to keep pace with the daily progress of discovery; and improvement, and ignorance of the results already obtained in any department, naturally necessitates a loss of valuable time and labour to those engaged on the subject. The bulk and variety of chemical literature are not, however, the only obstacles to the student; the difficulty is greatly increased to an Englishman by the fact that the greater part of this literature is published on the Continent, and appears in a variety of languages with which the average Englishman has but little acquaintance.

With such difficulties to encounter, the individual student has certainly little prospect of successfully keeping abreast with modern chemistry. We are therefore exceedingly glad to find that the matter has been taken up by the Chemical Society of London, and that they now publish in their monthly journal * carefully prepared abstracts of all the original papers which appear in foreign and English periodicals. The abstracts are classified for facility of reference, and are divided into Physical, Inorganic, Mineralogical, Organic, Physiological, Agricultural, Analytical, and Technical Chemistry; it is, therefore, quite easy to ascertain what has been recently done in any department of the science. When we mention that the volume for last year consists of 1,300 pages, and contains, besides the papers and lectures read before the Society, about 1,500 abstracts of chemical papers published in other journals, we shall give some idea of the magnitude of the work which the Society has undertaken.

Looking carefully through the journal we find that nearly 40 periodicals are regularly abstracted; and as many of these periodicals reprint papers from other less known publications, the extent of literature brought under contribution is very considerable. The periodicals abstracted are German, French, Italian, American, and English, the first two preponderating. The preparation of the abstracts is of course laborious, and demands considerable care. It is accomplished by a body of twenty-six abstractors, chiefly Fellows of the Society, whose initials are appended to their respective work. We are bound to say that the abstracting so far as we have had an opportunity of judging, is exceedingly well done.

A work of this kind is far too expensive to be permanently carried on by a Society destitute of endowment, unless the scientific public in our own and other countries cordially support the enterprise. We understand that the sale of the journal outside the circle of the Society is at present very small, and that the expenses of publication are largely borne by a guaranteed fund raised to give the journal a fair start, and also by a grant from the British Association. We feel sure that the enterprise needs only to be widely known to obtain the support of all lovers of Science. What the Chemical Society is now doing is indeed exactly what we most need in the present day to assist the multitude of workers who are employing scientific facts and methods. It is a kind of work which must sooner or later be carried further, and extended to all the principal sciences, if ourselves and successors are to cope with the ever-increasing accumulation of facts. While such abstracts are, from their early intelligence and their widely gathered and condensed information, an unspeakable boon even to the independent and educated philosopher, they are of still greater value to the ordinary worker, who has not the advantages of a large and costly library, or of an education embracing many languages; to him these abstracts, obtainable at moderate cost in his own language, supply as far as possible the absence of fuller means of information. The work which the Chemical Society has taken up receives, therefore, on many grounds our warmest sympathy. It would indeed be a disgrace to the intellect of our country if such a genuine effort were allowed to drop for lack of support. We would especially invite the attention of our American readers to this monthly journal; supplying, as it does, in their own language a summary of the chemical literature of Europe, we should think it would exactly meet their wants. The Germans have long had a yearly volume of abstracts treating of chemistry and its allied sciences; up to the commencement of the present publication the German *Jahresbericht für Chemie* was indeed the only available work giving a summary of recent investigations. This annual periodical has lately fallen so behind in date (the volumes for 1870 were only obtainable in the middle of last year), that it has really become a chronicle of the past, rather than of the present state of science, and can hardly compare with the new English work. The subscribers to the "Journal of the Chemical Society" possess indeed at the

* "The Journal of the Chemical Society," containing the papers read before the Society, and Abstracts of Chemical Papers published in other Journals. Edited by H. Watts, F.R.S. (J. Van Voorst, 1873.)

present time abstracts of about 4,000 papers, all of later date than those noticed in the last German *Jahresbericht*. Our German fellow-workers may therefore, with advantage to themselves, give their support to this English work.

We trust that the appreciation of all interested in chemical science for this most useful work will be so decidedly shown that the Chemical Society will soon have no further anxiety as to the success of their undertaking. The circle of readers appealed to is a very wide one; not only is it an absolute necessity for those who work at Science and those who profess it, but the medical man, the agriculturist, the manufacturer, and the geologist will all find an abundance of matter interesting to their special pursuits.

TODHUNTER'S "MATHEMATICAL THEORIES OF ATTRACTION"

A History of the Mathematical Theories of Attraction and the Figure of the Earth from the time of Newton to that of Laplace. By I. Todhunter, M.A., F.R.S. Two vols. (London: Macmillan, 1874.)

I.

THE late Prof. de Morgan, in his "References for the History of the Mathematical Sciences," divides the written histories into two classes, those which are written on the plan of Montucla, Bossut, &c., in which a general account is framed out of the writer's notes or remembrances of miscellaneous reading; or in that of Delambre, Woodhouse, &c., in which the successive writings of eminent men are examined and described one after the other, so that each chapter or section is a description of the progress of Science in the hands of some one person, and is complete in itself. This latter plan is the one he considers the most favourable to accuracy and the most interesting to students who are desirous of being the critics of the historians, and of amending their works, if need be. The admirable two volumes before us would certainly be placed under this head. As to the utility of such works, our author remarks: "A familiarity with what has been already accomplished or attempted in any subject is conducive to a wise economy of labour; for it may often prevent a writer from investigating afresh what has been already settled; or it may warn him, by the failure of his predecessors, that he should not too lightly undertake a labour of well-recognised difficulty." Mr. Todhunter is no novice in this style of writing; his "History of the Calculus of Variations" appeared in 1861, and at once placed him in the foremost rank of mathematical historians; this work was followed, in 1865, by the "History of the Theory of Probability." The principles upon which these earlier works were written have been adopted in the work under consideration. Experience has improved his already first-rate powers of analysis and of graphic representation of the contents of the works he considers; all that he wants is leisure; possibly a time may come when the University of Cambridge will appoint an historian (or historians) to fill up the painfully patent void which now exists in this department of literature. The acknowledged high merits of his published histories would suggest Mr. Todhunter as a most fitting first occupant of such a chair; the liberality of the syndics of the University Press in defraying the expenses of the printing of this last work affords evidence that the work is appreciated. In his recent volume of "Essays" (p. 151), our author mentions his taste for the history of Mathematics; we heartily hope that the union of such taste and mathematical powers will result in the begetting a numerous progeny all equally comely with, and of as good disposition as, the elder members of the family.

There is one feature in these histories that especially commends them to our own mind, and that is the writer's *candour*. We cannot better express our own views upon this point than by citing the following passage from the late Sydney Smith's writings: "There is nothing more beautiful in science than to hear any man candidly owning his ignorance. It is *so* little the habit of men who cultivate knowledge to do so—they so often have recourse to subterfuge, nonsense, or hypothesis, rather than to a plain manly declaration, either that they themselves do not understand the subject, or that the subject is not understood—that it is really quite refreshing to witness such instances of philosophical candour, and it creates an *immediate* prepossession in favour of the person in whom it is observed." * It is the absence of this candour which has been productive of so much confusion in this subject of mathematical history: the straining after completeness leads to the insertion of second- and third-hand descriptions; the right rule seems to be that of De Morgan and our author, "to give no opinion or account of any book whatever unless such as is derived from personal acquaintance with its contents." Extreme care and painstakingness are manifest throughout without any sign of flagging. Interesting as Mr. Todhunter's histories are, even to the general student, from the many "sidelights' they contain, and which are especially numerous in the present work, they are exceedingly valuable to the special student, on account of the investigations with which they abound. These are not mere reproductions, but they translate, as it were, the old and now almost obsolete language of the earlier writers into the language of modern analysis: thus in § 443 it is remarked of D'Alembert's notation, "It is not very inviting, and he leaves it to explain itself." Some idea of the extent of these investigations may be got from the fact that 475 out of the 1,632 articles are devoted to them.

The author's design is to write the history of the Mathematical Theories of Attraction and of the Figure of the Earth; for this purpose, he says, he has endeavoured to include all the memoirs and works which relate to these subjects. Such has been his diligence in his seven years' research, that we should suppose few books have escaped his notice: certainly none that would materially affect the conclusions he has arrived at. That he would have added a few to his list had he consulted the British Museum library, or had access to that bequeathed by the late Mr. Graves † to University College, we shall probably show in the course of this notice.

Mr. Todhunter shows that the subjects treated of are of no common importance and influence. Researches into both theories have been fertile in yielding new resources for mathematicians: it will suffice to instance

* "Conduct of the Understanding."

† We are informed that the liberality of a gentleman who has already been a great benefactor to the College will shortly enable students to get an accurate idea of the treasures contained in the above library.

the Transformation of Multiple Integrals, the theory of the Potential, and the functions of Laplace. A knowledge of the figure and dimensions of the earth forms the basis of all the numerical results of Astronomy. In § 25 he carefully defines the several terms made use of in the two subjects, equating in a useful way the varying terms employed by different writers.

The foundation of our subject, as all our readers know, is "great Newton's own ethereal self," Newton, "the crown and glory of his race." "The propositions on Attraction are numerous, exact, and beautiful; they reveal his ample mathematical power. The treatment of the figure of the earth is, however, still more striking, inasmuch as the successful solution of a difficult problem in natural philosophy is much rarer than profound researches in abstract mathematics. Newton's solution was not perfect; but it was a bold outline, in the main correct, which succeeding investigators have filled up but have not cancelled. Newton did not demonstrate that an *oblatum* is a possible form of relative equilibrium; but, assuming it to be such, he calculated the ratio of the axes. This assumption may be called Newton's *postulate* with respect to the figure of the earth; the defect thus existing in his process was supplied about 50 years later by Stirling and Clairaut" (§ 44). Newton appears to have arrived at his theorems in attraction in 1685; the first edition of the "Principia" made its appearance in 1687. (De Morgan, in his "Budget of Paradoxes," p. 81, discusses some of the sources of the apple story.)

Mr. Todhunter nowhere takes account of theories maintained before the time of Sir Isaac Newton; these were, for the most part, if not entirely, non-mathematical. A sketch is given in Book III. of Maclaurin's "Account of Sir Isaac Newton's Philosophical Discoveries, in Four Books."* We draw attention to this work because no reference is made to it in the *History*, whereas great part of Books III. and IV. is devoted to the subject of gravitation.

The same reason (for we cannot suppose Mr. Todhunter not to have consulted the work) has possibly induced him to pass over in silence the "Theoricæ Mediceorum Planetarum ex causis Physicis Deductæ"† of Borelli, though Libri, in his Catalogue, states that this writer "uses the principles of the law of Attraction as afterwards promulgated by Sir Isaac Newton."

Hardly a subsequent chapter but contains from one or another writer an acknowledgment of Newton's high powers; we shall here content ourselves with citing only Laplace's warm eulogy:—"Cet admirable ouvrage contient les germes de toutes les grandes découvertes qui ont été faites depuis sur le système du monde;" and further, he says, that the first step thus made by Newton in the theory must appear immense.

Huygens next appears on the scene. Our author (§§ 64, 65) clears up one or two points, more especially the rightful claim to priority of Newton over Huygens; an error which crops up in Barlow's "Mathematical Dictionary" and Svanberg's work on the Lapland Operations.

From § 48 we gather that Mr. Todhunter has not seen the *Opera reliqua*. S'Gravesande, in the preface to vol. ii. (we quote from the edition Amstel, 1728, 4to.), says, "Tractatus de lumine et dissertatio de gravitate quæ ambo scripta gallice dedit auctor, quamvis primum ut ipse in hujus præfatione monet, in linguam latinam vertere sibi proposuerat:" the second is turned into Latin with title "De causâ gravitatis." The *præfatio* occupies pp. 95, 96, *dissertatio* pp. 97-116 with an *additamentum* down to p. 136, and there is a plate: the *De vi centrifugâ* occupies pp. 107-134.

* London, 1775. 3rd edit. 8vo.
† Florentiæ, 1666. 4to.

In the *Opuscula postuma* (Lugd. Bat. 1703, 4to.) the treatise *De vi centrifugâ* (pp. 401-428) is founded, if we mistake not, on a different view of gravitation from that assigned to him by Mr. Todhunter in § 50.

Miscellaneous investigations, up to the year 1720, are then considered: Burnet's "Theory of the Earth" is glanced at, Keill's examination of the same, David Gregory's writings (which contribute nothing new), Hermann, Mairan ("Misapplied Mathematics and Misplaced Ingenuity") and the Cassinis, under whose powerful influence doubts arise as to the real shape of the earth, are more fully discussed.

We proceed to Maupertuis, a memoir* by whom is said (§ 128) to be the first example of the adoption of the principle of attraction by French mathematicians. We offer here a collation of the first editions of two of his works with the second editions which Mr. Todhunter discusses (§ 143).

The *avertissement* of 3 pp. in the 1738 edition of the *Examen désintéressé* is not reproduced in the 1741 edition: the 82 pp. of text, as also the 3 pp. of contents, at end, and the one page of errata, appear to be identical with the matter in the later edition. For the *Examen des trois*, &c., the bookseller's *avertissement* (4 pp.) is common to both: the 42 pp. of text appear to be the same; there is no list of errata; the foot-notes of the later edition appear as side-notes in the 1738 copy. The copy we consulted had the two essays bound up together, and is a duodecimo volume.

In the "Philosophical Dissertations on the Uncertainty of Human Knowledge" by the Marquis d'Argens, author of the "Jewish Spy," to which is added M. Maupertuis' "Dissertation upon Gravity,"&c.,translated from the French edition, in 2 vols. 1753, with the running title "The Impartial Philosopher," we have the following:—"After M. Maupertuis had examined the Newtonian system and after he had undergone infinite dangers and difficulties in the frozen regions of the North, in verifying a particular part of it, he concludes that we may look upon gravity as a power diffused through all parts of matter by which all its particles attract each other. The concurrence of all the force of matter which composes the earth, attracts and causes bodies to fall towards its surface, keeps the moon in her orb, and produces with regard to the other planets, and with respect to the sun, the like phenomena, always in proportion to the quantity of their force, their direction, and their distance" (pp. 255-263).

Whilst treating of Maupertuis, we think we have seen in the Graves' library the English translation of his "La figure de la terre . . . au cercle polaire," 1738: possibly the extract cited above is taken from it. In § 149 Mr. Todhunter says "Childrey seems" &c.: Joshua Childrey, 1623-1670, was of Magdalen College, Oxford, Archdeacon of Salisbury, 1663. He wrote "Britannia

* "Sur les loix de l'attraction:" cf. Bailly.

Baconica, or the Natural Rarieties of England, Scotland, and Wales, according as they are to be found in every Shire." (London, 1660. 8vo.) The passage referred to in the *Examen désintéressé* we presume was taken from the Paris edition (1667. 12mo.), under Carnarvonshire (pp. 244, 245 of the French, pp. 147, 148 of the English edition). In his dedication he writes:—"The calling I have entred into, and the capacity * wherein I have the honour to serve your Lordship, wil (I fear) offend the weake tendernesse of some, who think these deep searches into reason misbecoming a Preacher of Faith, and the contemplation of the works of Nature very impedimentall (if not destructive) to the work of Grace," &c.

Stirling (whom his rival Clairaut calls "one of the greatest geometricians I know in Europe") enunciated without demonstration approximate propositions respecting the magnitude and the direction of the attraction of an homogeneous *oblatum* at its surface and *implicitly* (§ 156) established Newton's *postulate*.

We now proceed to give an account of the original work (not seen by Mr. Todhunter) entitled "Dégré du méridien entre Paris et Amiens." (Paris, 1740.) It has 6 pp. of contents:—lvi. pp. of Part I. in nine chapters, with 3 pp. of plates. Part II. is "Mesure de la terre" par M. l'Abbé Picard, 106 pp., with 10 pp. on Aberration of fixed stars, and 5 pp. of fixed plates. On p. vi. we find, "le dégré comparé à celui que nous avons mesuré au cercle polaire, que nous avons trouvé de 57437, 9 toises donne la terre aplatie vers les pôles; et le rapport de l'Axe au diametre de l'equateur, comme 177 à 178." We had some difficulty in finding the book in the Museum from Mr. Todhunter's description; at last we found it catalogued under the heading Picard.

The Museum copy of the Essay by Celsius (§§ 198, 739, not seen by our author), entitled "De Observationibus," &c., Upsaliæ, 1738, is bound up with several other tractates on our subject, but all the rest partake of the character of the ante-Newtonian writers. Thus Nicolaus Winterberg (1596) heads his chapters—"Rotundam esse (terram) liquido apparet;" "Terram cum aquâ conjunctam σφαιροειδῆν asserimus;" and he further maintains the earth to be the centre of system of universe. We need not give an analysis of Celsius's work here; for this is undoubtedly the original from which the German translation, discussed by Mr. Todhunter, was taken. He styles Newton "vir immortalis," and, deciding against James Cassini, thus ends his ten-page tract—"Spero itaque me jam æquo et candido lectori satis superque ostendisse observationes Cassinianas, tam cœlestes quam terrestres in Gallia præcipue meridionali habitas, adeo incertas esse et inde figura telluris nullo modo deduci queat."

We have now arrived at the period when the question between the Newtonians and Cassinians was decisively settled, and the victory of the *oblates* over the *oblongs* acknowledged even by the Cassinis. This result was brought about by the expedition to Lapland in 1736-37, and won for its ruling spirit, Maupertuis, Voltaire's witty compliment of having "aplati les pôles et les Cassinis."

R. TUCKER

* He was chaplain to the "Rt. Hon. my most noble Lord and Master Henry Somerset Lord Herbert, &c."

OUR BOOK SHELF

Elements of Chemistry, Theoretical and Practical. By William Allen Miller, M.D., LL.D. Part II. Inorganic Chemistry. Revised by Herbert McLeod, F.C.S., Professor of Experimental Science, Indian Civil Engineering College, Cooper's Hill. 5th edit., with additions. (London: Longmans, 1874.)

IT will of course be superfluous to say anything in the way of criticism concerning this well-known manual. The death of its lamented author has necessitated the placing of the fifth edition in other hands, and it could not have fallen into better than those of its present editor. The principal changes so far have been a re-arrangement of the articles in accordance with the modern method of study and the removal of certain parts, such as those on gas analysis and the description of certain carbon compounds, to the appendix preparatory to their removal to the third part, to which they more strictly belong.

Some of the constitutional formulæ, now so much in use, have been introduced, and the kind selected have been those used by Frankland in his well-known "Lecture Notes." We are, however, glad to see that these have not been used to the exclusion of the notation adopted in former editions.

Great credit is due to Prof. McLeod for the thorough and conscientious way in which he has performed his task, and the only fault we have to find is that there is occasionally a certain amount of confusion caused by the use of different names for the same body, a fault for which, however, the science itself is largely responsible.

R. J. F.

Zones of Parallel Lines of Elevation in the Earth's Crust. By Angus Ross, sec. and mem. com. N. S. Inst. of Nat. Science. (Halifax, Nova Scotia, 1872.)

HE is a bold man who will predicate that no future discovered fact will disturb even the most widely accepted hypothesis. This being so, all hypotheses being in fact tentative only, and valuable in so far as they enable us to classify and deduce laws from such facts as we know, we ought to welcome every generalisation which groups known facts under some new aspect. In the above pamphlet we have such a generalisation. Whether it will prove to be supported by future discovery, or even whether it can be rigidly applied to explain actual facts will require much close criticism to determine. We can only say that it is ingenious and novel. The author claims to have discovered the method of distribution of the various mountain chains or lines of anticlinal elevation. These he asserts are arranged in parallel lines along certain belts or zones which girdle the earth, each zone following approximately the course of a great circle, and each having for its medial line or axis a line of volcanoes. Of these zones he describes seven, and we may extract one as a type of the rest. "Zone No. 1 on the Rocky Mountain system has its axial line in the volcanic belt extending from the middle Andes, inclusive, across Central America along the Rocky Mountains, Alaska, the Aleutian Islands, Kamtschatka, the Kurile Islands, Japan Islands, Loochoo Islands, Philippine Islands, Palawan, and Borneo. The Islands of Amsterdam and St. Paul, the Kerguelen Islands, the South Sandwich Islands, and South Georgia seem to indicate the completion of the more southerly part of the (approximately) great circle." The author, as we have said, describes seven such zones or belts which intersect one another, and argues that the points of intersection are foci of volcanic energy. He argues also that the great mountain-chains in their direction follow the course of one or other of these zones, and thus describes their arrangement:—"In each zone the proximity and elevation of the anticlinals diminish gradually from the axial line outwards, and if zone No. 1 be considered the most recent,

and the others as successively less recent in the order in which I have named them, and comparing similar parts of any two zones, the height of the anticlinals is greater, the dip less, and the difference between their axes greater in the more recent." The pamphlet is ably written and very deserving of study. HENRY H. HOWORTH

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Animal Locomotion

IN NATURE, vol. ix. p. 301, there is a letter from Mr. Wallace on a very important point connected with the Theory of Flight. The question he discusses is "whether a bird's wing during onward flight moves *downwards and backwards* or *downwards and forwards*;" and Mr. Wallace supports Mr. Pettigrew in affirming that the movement is *downwards and forwards*.

As this is a subject to which I have paid long and close attention, I desire to express my conviction that neither of the two motions thus described by Mr. Wallace is the true motion of a bird's wing in forward flight.

The true motion is one strictly vertical to the axis of the bird's body; and as that axis is ordinarily horizontal in flight, the wing-stroke is a vertical stroke, that is simply downwards, and neither "downwards and forwards" nor "downwards and backwards."

This is not a question of theory, but a question of fact, to be determined by observation. The wing-stroke of most birds is indeed so rapid that the eye cannot distinctly follow the operation. But there are birds whose wing is so large and whose flight is so slow, that the wing-stroke can be followed with the greatest distinctness. Such is the common heron—common, alas, no longer in most parts of England, but numerous on the west coast of Scotland. When at home I am in the daily habit of watching their flight; and the truly vertical character of the wing-stroke is a fact which I have verified by the eye under every possible condition which could supply the evidence.

There are indeed two slight modifications of the perfect perpendicularity of the stroke which result (1) from the attachment of the wing to the body of the bird, and (2) from the structure of the wing-feathers. The first of these two modifications consists in this—that as the wing moves upon a hinge, its extremity must move downwards, not absolutely vertically, but describing an arc. The segment of a circle, however, through which the wing thus moves, is generally a very short one: and in so far as the movement of the extremity departs from the vertical, it departs therefrom neither "backwards" nor "forwards," but (as it were) "inwards,"—that is, in the direction of a circle encompassing the axis of the bird's body as with a hoop. Pigeons, as an amusement and in play, often complete this circle—making their primary quills clash against each other over their backs, and downwards again under their breasts. But in ordinary forward flight, when birds are intent only on progression, the wings move through a very small arc indeed of the complete circle referred to.

The second modification of the perpendicularity of the stroke arises from the "set" of the wing-feathers—which curve backwards and downwards from the wing-bones. In some birds, and notably in the heron, and all the storks, the concavity thus formed is very deep, and of course a surface which is thus not a plane surface, but a concave one, however truly it may be struck downwards, cannot have a purely vertical reaction on the air.

When we observe, however, that in the case of many birds, and some of these the most powerful fliers in the world, this concavity of the wing-feathers is very slight indeed, and that the whole vane is very narrow, flat, and "taut," it is obvious that a purely vertical stroke, or one as near it as possible, is the really essential stroke for flight.

The great secret of flight is the exquisite and complicated adaptation of structure in the feathers of a bird's wing which derives from this one simple action the resultant of a force which is both sustaining and propelling. It is an adaptation which, when thoroughly grasped and understood, at once dispenses with as needless, and condemns as mechanically erroneous, all the explanations which assume either a "downward and forward" or a "downward and backward" movement.

I venture to think that Mr. Wallace is certainly in error when he ascribes to Mr. Pettigrew the merit of having been the first to show that "horizontal forward motion is a general resultant of the upward and downward action of the wings under the influence of gravitation."

In February 1865 I published in *Good Words* a paper on the mechanism of flight, in which this effect of the wing-stroke was fully explained, and elaborately illustrated. This paper subsequently appeared as chap. iii. in the "Reign of Law" published in the end of 1866. Mr. Pettigrew's lecture before the Royal Institution (in which I believe his views were first promulgated) was delivered on March 22, 1867. I had the pleasure of hearing that lecture, and the amusement of recognising parts of it (including even a poetical quotation) as taken directly from my chapter on flight. The pleasure, however, was somewhat abated by the strange mixture of much that was quite correct, with a great deal more which I believed then, and believe now, to be wholly erroneous. ARGYLL

March 11

MR. WALLACE has well said that the question, How a bird's wing moves in flight, "is a very important question." In these days, when scientific attention is being directed to the problem of aërial navigation, it is especially important. I have the less hesitation, therefore, in troubling you with some further remarks in reply to the strictures of this very accurate observer.

At the outset I must deny that I assumed either that a bird's wing is inflexible or that it is a plane. Of its flexibility I had no cause for speaking at all; but so far from regarding it as a plane, I expressly objected to Dr. Pettigrew so representing it in his supposed refutation of the orthodox view. The point in dispute is entirely concerning the down stroke; against Mr. Wallace's account of the up stroke I make no objection.

First, what may we infer *à priori* concerning the down stroke? (1) Its efficiency is independent of the velocity of the bird: this is simply a consequence of the second law of motion. We have to suppose a bird fixed in still air, and to ascertain the effect which ensues on a downward blow of the wing. The subsequent forward velocity of the bird, so far as that depends on the down stroke, is but a consequence or an accumulation of these effects. It is thus only needful to analyse the single effect itself. To this end the shape and varying flexibility of the wing must be noted. Along the exterior margin we have a rigid area, comparable to the blade of an oar, and formed for the most part of bone, in the *top side* of which the rigid tubes of the primary and secondary feathers are inserted. On the under side of this, which we may term the oar part of the wing, there is thus a considerable concavity, the direction of which when the wing is extended is decidedly backward. The area towards the middle line of the wing is flat and horizontal, approximately so at all events, when the bird is freely suspended in the air. Of the posterior, the larger, half of the wing it is true, as Dr. Pettigrew says, that the aspect is forward, more especially in heavy birds with broad and rounded wings. The flexible extremities of the feathers readily turn upwards like vanes in the manner so well shown in Fig. 80 of Dr. Pettigrew's work. We may thus roughly distinguish four areas, beginning from the front: (*a*) the oar area; (*b*) the plane or flapping area; (*c*) the kite area; (*d*) the vane area. (2) Now we may inquire what will be the effect of each when the wing is struck downward. The reaction from the oar area will be (*a*) a force directed upwards and forwards; that from the plane area (*b*) a force directed upwards simply. Against the kite area will impinge the air sent backwards and rebounding from the blow of the oar area; the effect of this (*c*) is all that corresponds to what Dr. Pettigrew calls the kite action of the wing. Lastly, the same air in escaping through the feathers, and especially in raising the tips in the vane area, will produce the forward motion (*d*) to which Mr. Wallace refers, besides contributing something (*e*) to support the bird's weight. The horizontal component of (*a*) together with (*d*) will carry the bird forward. The slighter horizontal component of (*c*)—slighter because proceeding only from the rebounding air and from a yielding surface—will tend to hinder the forward motion: hence the absence, more or less complete, of this area in quick fliers. The forces (*b*), greater part of (*c*), and (*e*) will sustain the bird against gravity.

Neither Dr. Pettigrew, nor apparently Mr. Wallace, distinguishes the motion consequent on a surface striking against the air from that of a surface gliding through it. If I incline a sheet of paper to the horizon and let it slip from my hand it will descend with a similar incline towards the ground; but if, having stiffened it, I strike it against the air at the same inclination it will tend to rise in a direction at right angles to that inclination. The *blow*

directed downwards and backwards must give an impetus upwards and forwards; the *still surface* so directed will glide downwards and forwards. I do not deny that if the down stroke of the bird's wing be directed backwards, *beyond a certain angle*, the resultant motion will be, as Mr. Wallace says, "obliquely downwards." But why? Because all the sustaining forces above enumerated are so seriously diminished—the horizontal and forward forces, with the exception of (*d*), being increased—that, to use Mr. Wallace's words, "the surplus vertical reaction of the down stroke over the up stroke is no longer able to overcome gravity," which converts the bird's wings for the nonce into kites as it comes sailing downwards, making but an occasional strike, now that the horizontal effect of the wings is so great, to increase the obliquity of its descent.

But within the limits of this angle, whatever they be, the effect of a downward and backward blow must, on mechanical grounds, be in general such as I have said. For clearness' sake it may not be superfluous to note an ambiguity in the expressions "downwards and backwards," "downwards and forwards;" they may apply either to the direction of the surface of the wing or to the direction of the anterior margin. I maintain only that the direction of the surface—in some wings, merely that of the anterior portion of the surface—is downwards and backwards. The anterior margin, by the contraction of the great pectoral muscle, is drawn downwards and forwards, in which, by the way, there is the further advantage that less air will escape from under the wing in front.

But, secondly, what can we *observe* as to the down stroke? (1) A fact, pointed out to me by an anatomical friend—that the great pectoral muscle which depresses the wing is inserted into a crest situated on the upper and forward side of the head of the humerus, so as to tilt the under surface of the wing slightly upwards, *i.e.* give it a backward direction. (2) If the flight of rooks, or still better of pigeons, be watched from a window towards sunset, the position of the shadows on the under side of the wings will be found pretty conclusive as to their direction. (3) The forward inclination of the wings of a bird about to alight, which shows that the motion of the wings in such a position retards flight. (4) The action of heavy land or water birds, that have to attain some momentum by the use of both feet and wings before they can rise; here surely a forward blow against the air is manifestly absurd. (5) "The highly-inclined position of a hovering bird," noticed by Mr. Wallace, and not of the bird only, but of his wings.

Mr. Wallace's closing remark is both true and sound:—"A bird's wing is a highly complex apparatus, subject to a variety of flexures and motions in every feather." Still it is possible, even probable, that all this variety is referrible to a few simple principles. It is with these alone that I have ventured to concern myself. JAMES WARD

Trin. Coll., Camb., March 3

With reference to Dr. Pettigrew's letter in NATURE, vol. ix. p. 362, I cannot do better than ask him to read the two papers that I refer to in my former reply, which he has evidently not done.

The Moon's Want of Atmosphere

YOUR very suggestive review of Messrs. Nasmyth and Carpenter's work on "The Moon" leads me to propose an explanation of the absence of a lunar atmosphere, which I do not remember to have seen anywhere. The many arguments in favour of the temperature of the lunar surface being near or at the *absolute* zero, when added to the equally probable supposition that at the *absolute* zero all matter assumes the solid form, makes nothing more probable in my mind than that it is the consolidation from cold of all the previously existing gases and vapours of the Moon which has caused its atmosphere to disappear. Prof. Frankland's theory of the frozen condition of the lunar surface is evidently different from the above, and Lord Rosse's observations on lunar radiation apply only to the direct reflection of the solar rays. A. H. GARROD

On Volcanic Eruptions

A PASSAGE in Nasmyth's work on the "Moon" suggests, as a consequence, an explanation of volcanic eruptions that I have often given in lectures. The point to be explained is, why they are sudden and intermittent. Processes of cooling and expansion are gradual.

I postulate (1) that a solid crust is shrinking as it cools; (2) that the liquid interior expands on solidifying; (3) that the melting-point of lava is lowered by pressure.

Let us start with a volcanic vent in which the aperture has become partially stopped by cooled or solidified lava. In the region below, pressure sets in from the cooling and ultimate solidification of part of the liquid mass. Hence the melting-point of the rest is lowered by (3). The process continues until the pressure becomes sufficient to relieve itself through some vent, old or new; a lava rises in the vent. But this relieves the pressure, and it follows from (3) that more rock will solidify, *suddenly*, and in so doing force liquid rock *rapidly* up the vent.

A volcano is, in fact, a geyser of lava.

I do not remember to have seen this in any book; and it perhaps would have been hazardous to assert postulate (2) as certainly true previous to Nasmyth's experiments; but I have thought it probable: and if it is true, postulate (3) follows, I believe, from the laws of heat, and the explanation will be sound. I shall be glad to hear what is thought of it by authorities.

Rugby, March 13 J. M. WILSON

Remarks on Ozone

HAVING perused Dr. Moffatt's interesting communication on Ozone in the *Scottish Meteorological Journal* of October last, and also noticed the paragraph on the subject in the *Medical Times* drawing attention to it, I beg to send the following remarks respecting some points in it open to criticism from outsiders:—

1. The numbers, and special *years of records*, are not stated in the statistical tables, which might be of importance for comparison with other persons' records.

2. The occurrence of ozone with *hail*, and not with snow, may be explained by its happening in warmer weather, and not in winter, and in the warmer stratum of air through which the hail falls from the cold stratum above.

3. The larger quantity of ozone in Table II. in *winter over that in summer* is anomalous, and inconsistent apparently with the records in Tables VI. and VII., where it is stated to increase with the temperature.

4. If ozone be thought to increase in quantity with *increase of elevation* above the level of the sea, it may be asked how that is to be reconciled with the greater prevalence of it at the sea-shore than inland.

5. If there be only an apparent connection between *electrical storms* and ozone, explanation may be required to account for the production of artificial ozone by electrical action, and whether the two be identical in constitution if not in origin.

6. The paragraph—"The *air is drier* near the tropics than about the equator," might be more clearly defined by adding the "tropical circles of cancer and capricorn," as within those lines it certainly gradually gets more and more humid.

7. In one paragraph there is stated to be an intimate connection between *humidity* of the atmosphere and the manifestation of ozone, and in another this is stated to be purely accidental, which is ambiguous, while the testimony in support of it is not in accord with that in Tables IX. and X., where the adverse record is apparent.

8. That the absolute *humidity of the air* diminishes with increase of elevation may be true in the case of lofty balloon ascents, away from any terrestrial influences of mountains, but, as pointed out in a note, the *relative humidity* increases, as we may see in Westmoreland or Dartmoor, where the heights are always misty and damp.

9. The tropical or *trade winds* only chance to be land winds in some such regions as the North Indian Ocean, whereas they are generally said to be sea-breezes, as in the South Atlantic Ocean, in the ordinary acceptation of the term.

10. The connection of the production of ozone by the means of *turpentine* will bring to the mind of the tourist the freshness of the air of hills planted with pine forests.

11. Accepting the theory that ozone is connected with the equatorial winds, it may be asked how the increase of ozone in the *calm belts* is to be accounted for, where there are only Polar winds, converging to ascend into the upper regions of the air from north and south.

12. The table of *observations at sea* on board ship would require to be supplemented by a note of the period of the year and number of days on record, as the quantity of ozone is already stated to vary with the *seasons of the year* (Table II.), and

the winds, temperatures, and barometrical indications might have been added for the like reason.

13. Table XI. also requires a note of the season of the year and the number of days of observations. It may here be asked, how is the discrepancy to be reconciled between the lessening of ozone as you sail *to the Polar Regions*, and the increase of ozone as you ascend in the air, when the temperature as regularly falls in the one case as in the other.

14 The records showing the connection between *phosphorescence* and manifestation of ozone are very satisfactorily drawn out, and may probably become of much value in a new investigation.

15. The less prevalence of ozone in the higher *extratropical latitudes* may be due, as suggested in another case, to the dryness of the atmosphere impairing the *sensitiveness of the test papers*, so that for the present such deductions are under suspicion.

16. The idea that the prevalence of ozone is coincident generally with a *low barometer* seems well supported by the observations recorded, but some explanation will be required to account for its maximum occurrence with *south-east winds* in Tables IX. and XI., if one should accept the theory of its connection only with equatorial winds.

17. That its presence may be connected with *warm temperatures* of the air seems better established at sea than on land, as also its coincidence with *humidity of the air*, though this is somewhat vitiated by the conscientious suggestion that its manifestation may be due to the increased susceptibility of the test-papers when moist.

18. In the statement that ozone increases as you ascend *mountainous elevations*, it is not stated what winds were blowing at the time, which would appear to be necessary, if the idea of its prevalence with any particular wind were considered essential.

19. The key to the origin and prevalence of ozone in the atmosphere seems still undiscovered, and we do not yet appear to have determined if it belongs to aqueous vapour or a special wind, or whether it be an additional constituent of the air, like carbonic acid, or a floating entity, like a cloud.

The Limits of the Gulf Stream

As one of those engaged in the compilation of the Atlantic pilot-charts published by the Admiralty, on which are given the limits, velocity, and general features of the Gulf Stream, as well as the boundaries of the regions in which ice and icebergs may be fallen in with in the North Atlantic, I cannot allow the letter in NATURE (vol. ix. p. 343), by W. W. Kiddle, of the White Star Mail steamship *Oceanic*, to remain unchallenged.

The Gulf Stream and ice boundaries, delineated on the North Atlantic chart, referred to in that letter, are in their details transcripts from the Atlantic pilot-charts.

These details were the result of much patient investigation, and obtained from many sources probably unknown to Captain Kiddle; among the most valuable were the painstaking and sound observations made by members of the United States Coast Survey, and to be found embodied in the annual reports between 1843 and 1859; and especially from the exhaustive and learned work on currents, so well known to cultivators of nautical science, by the late Major Rennell.

If the average boundaries of the Gulf Stream cannot be laid down within reasonable limits from the authorities I have quoted, aided, too, by the many observations of ships of war, extending over the present century, I fear that Captain Kiddle's results will not assist us in a more accurate delineation.

It is, however, to be hoped that Captain Kiddle's information on the currents may be more reliable than that he has ventured upon giving with regard to the limits of iceberg-drift; here recorded facts are irresistibly against him. He has only to consult any North Atlantic memoir on the subject, and he will find that icebergs have been fallen in with so far south as 36° 10′ N., or 7° south of the high authority he quotes. I would refer him on this interesting subject, as well as how icebergs are found on the southern edge of the Gulf Stream, and why it is possible "that bergs could drift square across the heated waters of the Gulf Stream to lat. 39° N.," to a paper by the well-known W. C. Redfield, of the United States (reprinted in the *Nautical Magazine* for 1845), who gathered the facts that have simply been utilised in the Admiralty charts.

London, March 11 THOMAS A. HULL

The Great Ice-Age

MR. GREEN, reviewing Mr. J. Geikie's work on the "Great Ice-Age" (NATURE, vol. ix. p. 318), expresses the opinion that a glacial period must have been one of intense cold. This is the general opinion, and yet I think it can be shown to rest on a misconception. If the climate at any given elevation is cold enough to form glaciers, no decrease of the winter temperature will increase their magnitude; while on the other hand a low summer temperature is shown by the facts of physical geography to be eminently favourable to glaciation. This last may almost be called an identical proposition, for permanent snow means snow which lasts through the summer.

As Mr. Croll has pointed out, there have been periods where the sun's greatest and least distances were respectively greater and less than now. He thinks that a glacial period occurred when, in the course of the precession of the equinoxes, the sun's greatest distance occurred in the winter, so as to cause a *cold winter*. I think the true theory of the glacial climate is exactly the reverse of this: that is to say, it was caused by the *cold summer* which occurred when the sun's greatest distance was in the summer.

I have stated these views at greater length in the *Journal of the Geological Society of London*, 1869, p. 350.

Old Forge, Dunmurry, Co. Antrim, March 8 J. J. MURPHY

Mars

IN a most interesting article on the planet Mars, in your issue of NATURE for Feb. 19, which has just been shown to me, the Rev. T. W. Webb directs attention to the question of the colours of Mars being due to effects of contrast or not, and says—"Nor does it seem to have been noticed that no effect of contrast has been traced in the Polar snows."

Kindly permit me to inform Mr. Webb that, in a paper on Mars in the last volume of the "Monthly Notices of the Royal Astronomical Society," I expressly state that, "on May 14, 1873, the south Polar ice appeared (in an $8\frac{1}{2}$-inch silvered glass reflector, by Browning) of quite a pale sky-blue colour, evidently by contrast," and I may add that this effect I noticed also on two or three subsequent occasions.

Burton-on-Trent, March 12 EDWARD B. KNOBEL

POLARISATION OF LIGHT *

VI.

MENTION was made in the previous article of the bands produced in the spectra of polarised light. Beside the fact of the existence of these bands it has been found upon examination that the state of polarisation at different parts of the interval between two successive bands varies; and such an examination may be made by means of a quarter-undulation plate or a Fresnel's rhomb.

If we carefully examine the spectrum of light which has passed through a selenite, or other ordinary crystal, we shall find on turning the analyser that, commencing with two consecutive bands in position, the parts occupied by the bands and those midway between them are plane-polarised, for they become alternately dark and bright; while the intermediate parts, *i.e.* the parts at one-fourth of the distance from one band to the next, remain permanently bright. These are, in fact, circularly polarised. But it would be incorrect to conclude from this experiment alone that such is really the case, because the same appearance would be seen if those parts were unpolarised, *i.e.* in the condition of ordinary light. And on such a supposition we should conclude, with equal justice, that the parts on either side of the parts last mentioned (*i.e.* the parts separated by one-eighth of the interval between two bands) were partially polarised. But if we introduce a quarter-undulation plate between the selenite and analyser, with its axis inclined at 45° to that of the selenite, circular polarisation will be converted into plane and plane into circular. This being so, the parts which

* Continued from p. 326.

were originally banded ought to become bright and to remain bright, while those that were originally bright ought to become banded during the rotation of the analyser. The effect to the eye will consequently be a general shifting of the bands through one-fourth of the space which separates each pair. Further, as on the one hand plane polarisation is converted into circular right-handed or left-handed by two positions of the plate at right angles to one another; so on the other right-handed circular polarisation will be converted by the plate in a given position into plane polarisation having the vibrations in one direction, and left-handed into plane polarisation having the vibrations in a direction at right angles to the former. Hence, if the plate be turned through a right angle from the position first described, the band will be shifted in a direction opposite to that in which they were moved at first. In this we have evidence not only that the polarisation on either band is circular, but also that on the one side it is right-handed, while on the other it is left-handed.

All the phenomena hitherto described manifestly depend upon the internal structure of the crystal plate, in virtue of which it affects the vibratory movement of the ether within it differently in different directions. And seeing that most crystals, when broken, divide themselves naturally into smaller crystals having the same form, *i.e.* having their planes and edges similarly inclined, we are naturally led to conclude that the structure of these bodies may differ not so much in different parts, as along different lines or planes connected with the forms into which they break, or (as it is also described) with their planes of natural cleavage. And this suggests the question whether an uncrystalline body might not, by pressure, or strain, or other mechanical distortion, be caused to affect the motions of the ether within it in a manner dependent upon their direction, and in that way to exhibit chromatic effects with polarised light analogous to those described above. Experiment answers this question in the affirmative.

The simplest experiment in this branch of inquiry consists in taking a rectangular bar of ordinary glass; and having crossed the polariser and analyser so as to give a dark field, to strain the bar with both hands as if we were trying to bend it or to break it across. The side towards which it may be supposed to be bent is of course compressed, while the opposite is stretched out. Between these two there must be an intermediate band, more or less midway between the two, which is neither compressed nor stretched. The moment the strain is put upon the bar light will be seen to pass through the parts of the bar nearest to both sides, while a band remains dark midway between the two.

This shows that the mechanical strain has imparted to portions of the glass a structural character analogous, at all events optically, to that of a crystal. The effects may be increased and rendered more striking by placing the glass in a frame furnished with a screw, by which the rod may be firmly held and considerable pressure applied at particular points. When this is done the structural character becomes more completely developed, and the dark band is fringed with colours which appear to flow inwards or outwards according as the pressure is increased or diminished. A slightly different, but more effective, exhibition of chromatic polarisation is produced by squeezing a thick square plate of glass in a vice. In this case the pressure may be carried further without fear of fracture, and the chromatic effects heightened.

It is, however, well known that molecular forces, such as those due to heat and cooling, in many cases far transcend in intensity those which we can exert by mechanical arrangements. And, in fact, if a block of glass be unequally heated to a very moderate degree, the internal structural effects immediately reveal themselves by dark bands, which indicate the border land between strain and pressure. As the block cools, these landmarks gradually disappear, and the field becomes again uniformly dark. But by far the most splendid effects (and these are permanent) are produced by unannealed glass; that is, by glass which has been rapidly and therefore unequally cooled. When a mass of glass has been cast in a mould in the form of a thick plate, then whatever be the contour line, the outside will cool first and become a rigid framework to which the interior of the mass must accommodate itself. The nature and direction of the pressure at each point of the interior will be primarily dependent upon the form of the contour; and by adopting various forms of contour the most beautiful and varied figures with coloured compartments may be produced. The forms and colours of the figures produced by transparent bodies when submitted to polarised light have been conversely used as a means of measuring, with almost unparalleled accuracy, the mechanical pressures which such a body is undergoing.

Besides glass many other substances may be used as reflectors so as to produce polarisation; for example, leaves of trees, particularly ivy, mahogany furniture, windows, shutters, and often roofs of houses, oil paintings, &c., and last but not least the surface of water. In each of these cases when the reflected beam is examined with a Nicol the alternations of light and darkness are most strongly marked, and the colours (if a crystal plate be used) are most vivid, or in technical language the polarisation is most complete, when the light is reflected at a particular angle. In proportion as the inclination of the incident light deviates from this angle the colours become fainter, until when it deviates very greatly all trace of polarisation disappears.

It will be found very interesting to examine the polarisation of sunshine reflected from ripples on the surface of a lake, or better still from the waves of the sea, and its different degrees of completeness produced at the variously inclined portions of the waves. But without having recourse to nature on so large a scale, an artificial piece of water may be placed in our room. A tea tray will serve as well as anything else to form our little sea; and a periodic tap at one corner will cause ripple enough for the present purpose. The waves appear bright, and although brighter in some parts than others they are nowhere entirely dark. But on turning the Nicol round the contrast of light and darkness becomes much stronger than before. In parts the light is absolutely extinguished, or the polarisation is complete; in others it is incomplete in various degrees. And if a selenite or other crystal plate be introduced we have the beautiful phenomena of iris-coloured rings playing over the surface of our miniature sea.

Suppose that we now turn our attention to the sky, and on a clear bright day we sweep the heavens with a polariscope, or even with a mere Nicol's prism, we shall find traces of polarisation in many directions. But if we observe more closely we shall find that the most marked effects are produced in directions at right angles to a line drawn from our eye to the sun, when in fact we are looking across the direction of the solar beams. Thus, if the sun were just rising in the east or setting in the west, the line of most vivid effect would lie on a circle traced over the heavens from north to south. If the sun were in the zenith, or immediately overhead, the most vivid effects would be found on the horizon; while at intermediate hours the circle of strongest polarisation would shift round at the same rate as the shadow on a sun-dial, so as always to retain its direction at right angles to that of a line joining ourselves and the sun.

Now, what is it that can produce this effect, or indeed, what produces the effect of light from all parts of a clear sky? The sky is pure space with no contents, save a few miles of atmosphere of the earth, and beyond that the impalpable ether, supposed to pervade all space, and to

transmit light from the furthest limits of the stellar universe. The ether is however certainly inoperative in the diffusion of light now under consideration. But a very simple experiment will suffice to show that such a diffusion or, as it has been better called, a scattering of light, is due to the presence of small particles in the air. If a beam from an electric lamp or from the sun be allowed to pass through a room its track becomes visible by its reflection from the motes of floating bodies, in fact by the dust in the air. But if the air be cleared of dust by burning it with a spirit lamp placed underneath, the beam disappears from the parts so cleared, and the space becomes dark. If, therefore, the air were absolutely pure and devoid of matter foreign to it, the azure of the sky would no longer be seen and the heavens would appear black; the illumination of objects would be strong and glaring on one side, and on the other their shadows would be deep and unrelieved by the diffused light to which we are accustomed. Now, setting aside the dust, there are always minute particles of water floating in the atmosphere. These vary in size from the great raindrops which fall to earth on a sultry day, through intermediate forms of mist and of fine fleecy cloud, to the absolutely invisible minuteness of pure aqueous vapour which is present in the brightest of skies. It is these particles which scatter the solar rays and suffuse the heavens with light. And it is a remarkable fact, established by Prof. Tyndall, while operating with minute traces of gaseous vapours, that while coarser particles scatter rays of every colour, in other words scatter white light, finer particles scatter fewer rays from the red end of the spectrum, while the finest scatter only those from the blue end. And in accordance with this law clouds are white, clear sky is blue.

But the point which most concerns us here is the fact, also discovered by Prof. Tyndall, that light scattered laterally from fine particles is polarised. The experiment by which this is most readily shown is as follows: Allow a beam of solar or other strong light to pass through a tube about thirty inches long filled with water, with which a few drops of mastic dissolved in alcohol have been mixed. The fluid so formed holds fine particles of mastic in a state of suspension, which scatter the light laterally; and if the scattered light be examined with a Nicol traces of polarisation will be detected. But better still, instead of using the scattering particles as a polariser and the Nicol as an analyser, we may polarise the light before it enters the tube and use the particles as an analyser, and thus produce the same effect as before, not only upon the particular point of the beam to which the eye is directed, but upon the whole body of scattered light. As the Nicol is turned the light seen laterally begins to fade; and when the instrument has been turned so as to cut off all vertical vibrations, the only parts remaining visible in a horizontal direction will be those reflected from the larger impurities floating in the water independently of the mastic. The direction of vibration of the light polarised by lateral scattering is easily remembered by the fact that the vibrations must be perpendicular both to the original and to the scattered beam; if, therefore, the latter be viewed horizontally, they must be perpendicular to two horizontal straight lines at right angles to one another, *i.e.* they must be vertical.

An effect still more beautiful, and at the same time perhaps more instructive, may be produced by interposing a plate of quartz between the Nicol and the tube. The whole beam then becomes suffused with colour, the tint of which changes for a given position of the spectator with the angle through which the Nicol is turned.

And not only so, but while the Nicol remains at rest the tints are to be seen scattered in a regular and definite order in different directions about the size of the beam. But this radial distribution of colours may also be shown in a more striking manner, by using a bi-quartz, which as explained before distributes the colours in opposite directions. The beam should in every case be viewed at right angles; the more obliquely it is viewed the less decided is the polarisation.

The colours here seen are those which would be observed upon examining a clear sky in a position 90° from that of the sun; and the exact tint visible will depend upon the position in which the Nicol is held, as well as upon that of the sun. Suppose, therefore, that a Nicol and quartz plate be directed to that part of the sky which is all day long at right angles to the sun, that is, to the region about the north pole of the heavens (accurately to the north pole at the vernal and autumnal equinox), then if on the one hand the Nicol be turned round, say, in a direction opposite to that of the sun's motion, the colours will change in a definite order; if, on the other, the Nicol remain stationary while the sun moves round, the colours will change in a similar manner. And thus, in the latter case we might conclude the position of the sun, or in other words the time of the day, by the colours so shown. This is the principle of Sir Charles Wheatstone's Polar clock, which is one of the few practical applications which this branch of polarisation has yet found.

Figs. 18 and 19 represent general forms of this instrument described in the following passage by the inventor.

"At the extremity of a vertical pillar is fixed, within a brass ring, a glass disc, so inclined that its plane is perpendicular to the polar axis of the earth. On the lower half of this disc is a graduated semicircle divided into twelve parts (each of which is again sub-divided into five or ten parts), and against the divisions the hours of the day are marked, commencing and terminating with VI. Within the fixed brass ring, containing the glass dial plate, the broad end of a conical tube is so fitted that it freely moves round its own axis; this broad end is closed by another glass disc, in the centre of which is a small star or other figure, formed of thin films of selenite, exhibiting when examined with polarised light strongly contrasted colours; and a hand is painted in such a position as to be a prolongation of one of the principal sections of the crystalline films. At the smaller end of the conical tube a Nicol's prism is fixed so that either of its diagonals shall be 45° from the principal section of the selenite films. The instrument being so fixed that the axis of the conical tube shall coincide with the polar axis of the earth, and the eye of the observer being placed to the Nicol's prism, it will be remarked that the selenite star will in general be richly coloured, but as the tube is turned on its axis the colours will vary in intensity, and in two positions will entirely disappear. In one of these positions a smaller circular disc in the centre of the star will be a certain colour (red, for instance), while in the other position it will exhibit the complementary colour. This effect is obtained by placing the principal section of the small central disc $22\frac{1}{2}°$ from that of the other films of selenite which form the star. The rule to ascertain the time by this instrument is as follows:—the tube must be turned round by the hand of the observer until the colour star entirely disappears while the disc in the centre remains red; the hand will then point accurately to the hour. The accuracy with which the solar time may be indicated by this means will depend on the exactness with which the plane of polarisation can be determined; one degree of change in the plane corresponds with four minutes of solar time.

"The instrument may be furnished with a graduated quadrant for the purpose of adapting it to any latitude; but if it be intended to be fixed in any locality, it may be permanently adjusted to the proper polar elevation and the expense of the graduated quadrant be saved; a spirit-level will be useful to adjust it accurately. The instrument might be set to its proper azimuth by the sun's shadow at noon, or by means of a declination needle; but an obser-

vation with the instrument itself may be more readily employed for this purpose. Ascertain the true solar time by means of a good watch and a time equation table, set the hand of the polar clock to correspond thereto, and turn the vertical pillar on its axis until the colours of the selenite star entirely disappear. The instrument then will be properly adjusted.

"The advantages a polar clock possesses over a sun-dial are :—1st. The polar clock being constantly directed to the same point of the sky, there is no locality in which

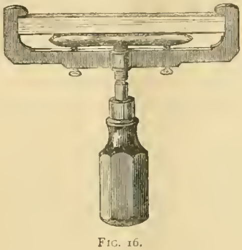

Fig. 16.

it cannot be employed, whereas, in order that the indications of a sun-dial should be observed during the whole day, no obstacle must exist at any time between the dial and the places of the sun, and it therefore cannot be applied in any confined situation. The polar clock is consequently applicable in places where a sun-dial would be of no avail ; on the north side of a mountain or of a

Fig. 17.

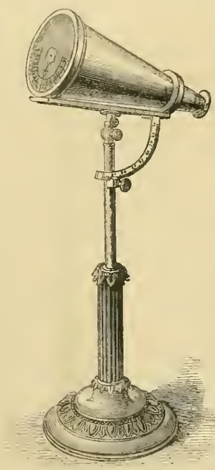

Fig. 18.—Wheatstone's Polar Clock.

lofty building for instance. 2ndly. It will continue to indicate the time after sunset and before sunrise ; in fact, so long as any portion of the rays of the sun are reflected from the atmosphere. 3rdly. It will also indicate the time, but with less accuracy, when the sky is overcast, if the clouds do not exceed a certain density.

"The plane of polarisation of the north pole of the sky moves in the opposite direction to that of the hand of a watch ; it is more convenient therefore to have the hours graduated on the lower semicircle, for the figures will then be read in their direct order, whereas they would be read backwards on an upper semicircle. In the southern hemisphere the upper semicircle should be employed, for the plane of polarisation of the south pole of the sky changes in the *same* direction as the hand of a watch. If both the upper and lower semicircles be gra-

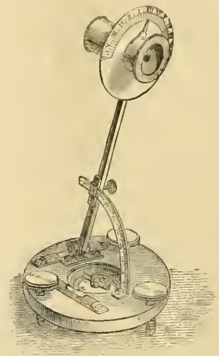

Fig. 19.—Wheatstone's Polar Clock.

duated, the same instrument will serve equally for both hemispheres."

The following is a description of one among several other forms of the polar clock which have been devised. This (Fig. 20) though much less accurate in its indications than the preceding, beautifully illustrates the principle.

"On a plate of glass twenty-five films of selenite of equal thickness are arranged at equal distances radially in a semicircle ; they are so placed that the line bisecting the principal sections of the films shall correspond with the radii respectively, and figures corresponding to the hours are painted above each film in regular order. This plate of glass is fixed in a frame so that its plane is inclined to the horizon 38° 32′, the complement of the polar elevation ; the light passing perpendicularly through this plate falls at the polarising angle 56° 45′ on a reflector of black glass, which is inclined 18° 13′ to the horizon. This ap-

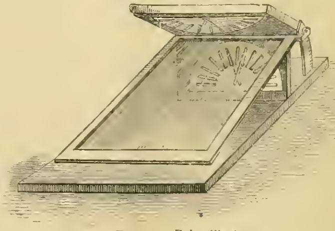

Fig. 20.—Polar Clock.

paratus being properly adjusted, that is so that the glass dial-plate shall be perpendicular to the polar axis of the earth, the following will be the effects when presented towards an unclouded sky. At all times of the day the radii will appear of various shades of two complementary colours, which we will assume to be red and green, and the hour is indicated by the figure placed opposite the radius which contains the most red ; the half-hour is indicated by the equality of two adjacent tints."

W. Spottiswoode

(*To be continued.*)

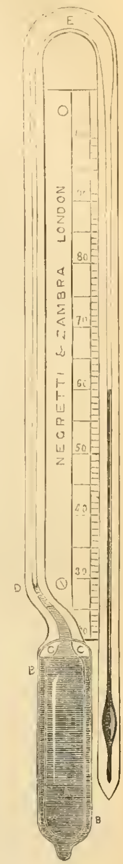
A NEW THERMOMETER

OUR readers will doubtless recollect a recent discussion in our pages relative to the priority of the invention of protected bulbs for deep-sea thermometers. The discussion has done something more than establish priority of invention, it has been the means of producing what, we believe, will prove to be a new and valuable meteorological instrument, for we have before us a paper by Messrs. Negretti and Zambra, communicated to the Royal Society by Dr. Carpenter at their last meeting, describing a new thermometer of such novel construction that it cannot fail to interest all scientific persons, meteorologists especially. We regret our inability, owing to want of space, to reproduce the paper in its entirety. The following are the main points of this communication.

In Prof. Wyville Thomson's "Depths of the Sea," p. 299, occurs the following passage :—"I ought to mention that in taking the bottom temperature with the Six's thermometer the instrument simply indicates the lowest temperature to which it has been subjected; so that if the bottom water were warmer than any other stratum through which the thermometer had passed, the observations would be erroneous."

Undoubtedly no other result could be obtained with the thermometers now in use, for unfortunately the only thermometer available for the purpose of registering temperature and bringing those indications to the surface, is that which is commonly known as the Six's thermometer—an instrument acting by means of alcohol and mercury, and having movable indices with delicate springs of human hair tied to them. This form of instrument registers both maximum and minimum temperatures, and as an ordinary out-door thermometer it is very useful ; but it is unsatisfactory for scientific purposes, and for the object for which it is now used (viz. the determination of deep-sea temperatures) it leaves much to be desired. Thus the alcohol and mercury are liable to get mixed in travelling, or even by merely holding the instrument in a horizontal position ; the indices also are liable either to slip if too free, or to stick if too tight. A sudden jerk or concussion will also cause the instrument to give erroneous readings by lowering the indices if the blow be downwards, or by raising them if the blow be upwards. It was on reading the passage in the book above referred to that it became a matter of serious consideration with Messrs. Negretti and Zambra, whether a thermometer could be constructed which could not possibly be put out of order in travelling, or by incautious handling, and which should be above suspicion and perfectly trustworthy in its indications. This was no very easy task. But the instrument submitted to the Fellows of the Royal Society seems to fulfil the above onerous conditions, being constructed on a plan different from that of any other self-registering thermometer ; and containing, as it does, nothing but mercury, neither alcohol, air, nor indices. Its construction is most novel, and may be said to overthrow our previous ideas of handling delicate instruments, inasmuch as its indications are only given by upsetting the instrument. Having said this much, it will not be very difficult to guess the action of the thermometer ; for it is by upsetting or throwing out the mercury from the indicating column into a reservoir at a particular moment and in a particular spot, that we obtain a correct reading of the temperature at that moment and in that spot.

The thermometer in shape is like a syphon with parallel legs, all in one piece, and having a continuous communication, as in the annexed figure. The scale of the thermometer is pivoted on a centre, and being attached in a perpendicular position to a simple apparatus (which will be presently described), is lowered to any depth that may be desired. In its descent the thermometer acts as an ordinary instrument, the mercury rising or falling according to the temperature of the stratum through which it passes ; but so soon as the descent ceases, and a reverse motion is given to the line, so as to pull the thermometer to the surface, the instrument turns once on its centre, first bulb uppermost, and afterwards bulb downwards. This causes the mercury, which was in the left-hand column, first to pass into the dilated siphon bend at the top, and thence into the right-hand tube, where it remains, indicating on a graduated scale the exact temperature at the time it was turned over. The woodcut shows the position of the mercury *after* the instrument has been thus turned on its centre. A is the bulb ; B the outer coating or protecting cylinder ; C is the space of rarefied air, which is reduced if the outer casing be compressed ; D is a small glass plug on the principle of Negretti and Zambra's Patent Maximum Thermometer, which cuts off, in the moment of turning, the mercury in the column from that of the bulb in the tube, thereby ensuring that none but the mercury in the tube can be transferred into the indicating column ; E is an enlargement made in the bend so as to enable the mercury to pass quickly from one tube to another in revolving ; and F is the indicating tube, or thermometer proper. In its action, as soon as the thermometer is put in motion, and immediately the tube has acquired a slightly oblique position, the mercury breaks off at the point D, runs into the curved and enlarged portion E, and eventually falls into the tube F, when this tube resumes its original perpendicular position.



The contrivance for turning the thermometer over may be described as a short length of wood or metal having attached to it a small rudder or fan ; this fan is placed on a pivot in connection with a second ; on the centre of this is fixed the thermometer. The fan or rudder points upwards in its descent through the water, and necessarily reverses its position in ascending. This simple motion or half turn of the rudder gives a whole turn to the thermometer, and has been found very effective.

Various other methods may be used for turning the thermometer, such as a simple pulley with a weight which might be released on touching the bottom, or a small vertical propeller which would revolve in passing through the water.

Messrs. Negretti and Zambra in their paper merely mention the new thermometer as being available for deep-sea temperatures ; but we believe it will prove to be of great value on land ; for with this thermometer we are at once provided with the means of making observations which will solve some of the most interesting questions connected with atmospheric temperature. At present we do not possess a *simple* instrument, in fact none at all which will automatically record *out of doors* the exact temperature at fixed periods ; we read of the temperature being so many degrees of heat or cold yesterday or last night, but we have no means of recording how cold it was (say) at midnight, or how warm at midday, except by actually watching the instrument at those hours. With the new thermometer in connection with an inexpensive time-piece, we can ascertain and re-

cord the exact temperature at any hour it may be deemed desirable, and by its means, and with experiments carried over some period of time, we may be able to determine with a degree of accuracy hitherto only approximately arrived at, which are the coldest or warmest periods of the days or nights.

ON SOME RECENT ASTRONOMICAL SPECULATIONS IN THEIR RELATION TO GEOLOGY*

I HAVE called my subject *speculations*, because in the present state of the inquiry there are so many questions that can be looked upon in no other light. At the same time it appears to me very desirable that certain facts should be examined from this new point of view, if only to lead to researches which otherwise would not have claimed attention. What I then propose is to consider the bearing on certain geological questions of the new views of Mr. Lockyer respecting the constitution of matter, as indicated by a comparison of the spectra of the various classes of stars, and the probable effects of a change in the constitution of our sun.†

Sir W. Thomson has contended that the sun cannot have continued to give out heat and light for so long a period as has been assumed by many geologists, and has concluded that it was "on the whole most probable that it has not illuminated the earth for 100 millions of years, and almost certain that it has not done so for 500 millions."‡ Prof. Huxley made this question the subject of his address to the Geological Society in 1869, but the argument on both sides was on the supposition that the constitution of matter is such that from the earliest epoch the heat and light given off had been derived mainly, if not entirely, from the simple cooling of a heated body. If, however, Mr. Lockyer's views be true, the sun at the earliest period must have consisted of matter in a more dissociated condition than at present, and, as he points out, in combining so as to give rise to other so-called elementary substances, probably a large extra amount of heat and light would be set free. The result of this appears to me to be that when the general temperature was that at which such a dissociation occurs, the sun's energy would continue nearly the same for a period which in the present state of our knowledge cannot be determined, but which would probably be of vast duration; and not only so, but the cooling would be more uniform from the first, and not subject to so great a variation as would occur in the case of an intensely-heated body cooling without any physical change in its constituents. If this be so, the length of time during which our globe may have been receiving such an amount of heat and light as would be compatible with the existence of animals and plants may well have been as great as that demanded by any of the supporters of evolutionary theories.

Though there would be such an approximate uniformity for a vast period, yet still at the earliest epoch, the physical state of the sun would not have been the same as now, and it becomes important to consider what effect this may have produced on life on the globe. According to Mr. Lockyer's views the sun at an early period had much the same physical constitution as the stars of the type of Sirius, giving off light of a whiter or bluer character, *i.e.* the rays at the blue end of the spectrum were relatively stronger than at present, whilst in future ages they would become more feeble, and the sun pass into the condition of stars of the red type. What then would be the effect of the greater intensity of the rays at the blue end of the spectrum on animals and plants at early geological epochs? This question clearly indicates the importance of future experimental inquiries, directed to this particular subject, but at the same time it may be well to consider the bearing of what is already known. In the present state of our knowledge no facts seem more likely to help towards a conclusion than those connected with the distribution in plants of the more important of the coloured substances which absorb different rays of light. I have found that there is an intimate relation between their optical and chemical characters, and that these are also related to the development of the individual plants, and to the structural development of mature plants of different classes. Taken as a whole, in advancing from a more rudimentary condition, there is in each case a farther and farther departure from such colouring-matters as can be formed artificially, and a relatively greater and greater production of those which are more and more easily decomposed by light, when not protected by the constructive energy of the living plants. This destructive action is due relatively more to the rays at the blue end of the spectrum, whilst, at all events in the case of chlorophyll, the production depends more upon the yellow rays. Hence, by relatively increasing the intensity of the blue rays the destructive force would be relatively increased, and the constructive force relatively diminished. We may, perhaps, therefore conclude that bluer light would be relatively more favourable to the higher classes of plants when in the early stage of their growth, and to the lower than to the higher classes when in the mature condition requisite to insure permanent reproduction. The former conclusion is borne out by Mr. Robert Hunt's experiments, which showed that whilst the rays at the blue end of the spectrum quicken the germination of the higher classes of plants, it is the rays at the extreme red end which facilitate their flowering and the perfecting of the reproductive organs.* The effect of differently coloured light on the growth of the cryptogamia has not, I believe, been examined; but, if the principles involved in the above arguments be correct, they would lead us to conclude that at an early epoch in the history of our globe the bluer light of the sun would be relatively more favourable to the growth of larger cryptogams than to that of phænogams. The arguments I have used do, however, involve so many new and imperfectly-tried general principles, that it would be very premature to say that the characteristic peculiarities of the vegetation of the earlier geological periods depended on this cause, and all that I contend is that the question deserves to be examined from this new point of view, since it may at all events assist in arriving at a true explanation.

* An abstract of a paper read before the Sheffield Literary and Philosophical Society, Feb 3, 1874, by H. C. Sorby, F.R.S.

THE "CHALLENGER" EXPEDITION†

II.

FERNANDO NORONHA

THIS group of islands was visited by the *Challenger* on September 1 and 2, 1873. They consist of a principal island, about four miles long, and three-and-a-half broad, stretching about N.E. and S.W., and several smaller ones at the eastern extremity, known as Platform Island, Booby Island, St. Michael's Mount, Egg Island, and Rat Island. They are situated in the Atlantic, in lat. 30° 50', about 200 miles from the nearest point of the South American coast, their entire length being about seven miles. The principal island is generally of a volcanic character, and hilly, the highest hill being about 600 feet. On its northern coast rises to a height of 1,000 feet what is known as the Peak. It is a peculiar-looking

† These Notes are founded on letters sent home by Mr. H. N. Mosely.

mass of bare rock, the summit of which is entirely devoid of vegetation, and quite inaccessible. The cliffs are composed of columnar basalt. At the eastern end of the island are some sand rocks, like that of Bermuda, and dunes of calcareous sand also occur. St. Michael's Mount is a cone 300 feet high, composed of a mass of phonolith. The remaining islands are flat, composed of sandstone, with volcanic particles.

It was in the dry season, which extends from July to December, that the *Challenger* visited these islands; this season, however, is not one of absolute drought, parching up everything, but there are occasional heavy rains. Trees abound on the higher parts of the island, where the land has not been cleared for cultivation, or where the convicts have not felled them for making their fishing-boats or rafts, the largest trees, it is said, having all disappeared for this purpose. Numerous creepers cluster together in the branches of the trees. At the western extremity of the island the vegetation is thickest and richest, and apparently of a virgin character. *Jatropha gossypifolia* L., a large shrubby plant, common in the West Indies, and also growing in Bahia, Mexico, and New Granada, was very abundant; it was in full flower, but its only foliage were tufts of young leaves just beneath the inflorescence, so that its bare stems were conspicuous among the green creepers. The plant was also found on St. Michael's Mount and Rat Island. Another euphorbiaceous-looking plant, with stout thorns, was found on the principal island, but not on any of the others. A thorny acacia also grew on the shore; and climbing round almost every tree was *Abrus precatorius* L., one of the commonest of tropical plants, and so well known for its pretty brilliant scarlet and black seeds, which are used everywhere for necklaces, and other ornamental purposes, and in India as a standard weight. This plant, however, grew only on the main island. *Ipomœa pes-capræ* Sw. is abundant on the sand hills, and upon it and most of the other low-growing plants, *Cuscuta americana* L., spreads amazingly. A species of *Cereus* was abundant on the cliffs, but only one grass (*Oplismenus colonus* H.B.) was found on the main island.

Trees, bushes, and creepers cover the upper part of St. Michael's Mount, which is, to a certain extent, inaccessible, and, moreover, being so small, offers no room for cultivation; therefore there is no reason to suspect that the plants found upon it are attributable to any other than a natural origin. *Capparis cynophallophora* L. grows in abundance on the summit of the mount. It is a tree with a stem 8 or 9 inches in diameter, and dark green oval lanceolate leaves. A species of Ficus with aerial roots grows in favourable spots, and there forms a tree of considerable size; one is mentioned as having a trunk 30 feet high, and 18 inches in diameter. On Rat Island the same species of Ficus was also found down near the sea level, where, instead of forming a tree, it becomes a low spreading bush, not more than 5 or 6 feet high. From the natural exposure of this island to the full force of the wind, all the plants growing here, which are mostly leguminous and euphorbiaceous, mingled with cucurbitaceous creepers, are stunted in their growth. Although shady moist places occur about St. Michael's Mount, neither on this nor on the main island were any ferns, mosses, or hepaticæ found. Lichens also are very scarce.

Among the principal cultivated fruits are bananas and melons, the latter being very plentiful, and of a peculiarly fine flavour. Grapes grow well, but are not cultivated at the present time. Sugar-cane, cassava, maize, sweet potatoes, &c. are also grown in large quantities.

Animal life is singularly scarce, two lizards being the only animals recorded from Fernando Noronha, one of which is peculiar to the island, the other being found also in North America.

NOTES

The following intelligence with regard to the late Dr. Livingstone, sent by Dr. Kirk, appears in the *Times* of Tuesday:—"Lieut. Murphy, in a note addressed to me from M'pwapwa, a place about ten days' journey from the coast, and dated the 20th of January last, says that he was then accompanying the body, and expected to reach Bagamoio, a seaport, on or about the 14th ult. Capt. Sheffe, of the Austrian ship-of-war *Heligoland*, had proceeded to the coast, and would at once convey the body and Lieut. Murphy's party to Zanzibar on their arrival. Lieut. Cameron had set out for Ujiji to recover papers left there by Dr. Livingstone. Lieut. Murphy had been in communication with him subsequent to the death of Dr. Dillon, and was sorry to find that great difficulties impeded his onward progress, owing to the antagonism of native chiefs and the desertion of many of his followers on the road from Unyanyembe to Ujiji. Chuma, who for eight years accompanied the Doctor in his wanderings, I learn had been into Zanzibar. He seems to place the position of Dr. Livingstone's death at the north of Lake Bangweolo, on or about the 4th of May, 1873. He was probably on his way westward. A reply to the official telegram, regarding the disposal of the body on arrival, was anxiously expected."

We learn that Mrs. Arnott, the widow of the late Dr. Neil Arnott, has written to Dr. Lyon Playfair, the member for the University of Edinburgh, offering 1,000*l.* for the promotion of Natural Philosophy in that University.

The trustees of the late Dr. Andrew Bell, the founder of the Madras School, St. Andrews, have placed at the disposal of the Senatus of the University of St. Andrews, his native city, a considerable sum towards the endowment of an Education Chair during the present session. The Senatus has had under consideration the subject of a teacher's degree, and a programme relating to its institution has been laid before the Education Department of the Government.

At a meeting of the Sedgwick Memorial Committee held at Cambridge on the 11th inst., Prof. Humphry in the chair, it was stated by the Treasurer that the subscriptions exceeded 10,000*l.*, and that more than 7,000*l.* had been paid into the account of the fund at the several banks. The question of the site of the new Geological Museum, which is to constitute the memorial, was discussed, and the feeling of the committee was in favour of the space in front of the New Museum and Pembroke Street.

The Italian Government has determined to send out four expeditions for the observation of the Transit of Venus, the main instrument of inquiry depended upon being the spectroscope. On the other hand, for reasons not far to seek, no spectroscopes are to be employed by the English parties. Truly "they manage these things better in France," and not only in France, but in America and Italy.

To-night (Thursday) Mr. Dewar's lecture On Dissociation will be given before the Chemical Society.

At the annual meeting of the trustees of the Museum of Comparative Zoology, Cambridge, U.S., held in January, a committee reported that to carry out the plan inaugurated by Prof. Agassiz, a considerably larger endowment will be necessary, and that the funds now on hand are not sufficient to conduct operations on the present scale later than April 1, after which, unless an additional income of 15,000 dols. can be secured, it will be necessary to greatly reduce the scale of work. 30,000 dols. per annum is estimated as being the least sum on which the establishment can be maintained on a satisfactory scale. Efforts are now being made to secure an endowment of 300,000 dols., of which about 65,000 had been contributed at a recent date.

THE Duke and Duchess of Edinburgh, on their visit to the Zoological Gardens on Sunday last, desired to have their attention specially directed to a deer sent from Manilla by his Royal Highness as a present. When it arrived in this country, in May 1870, Mr. Sclater, F.R.S., the Secretary to the Society, immediately recognised that it belonged to a species hitherto quite unknown, and he accordingly named it *Cervus alfredi* or Prince Alfred's Deer. It is a very interesting fact that this specimen, and one of the opposite sex subsequently purchased by the Zoological Society, together with a young one born in the Gardens, are the only examples that have at any time been obtained of this particularly well-marked species of deer.

THERE will be an election at Worcester College, Oxford, in June, to three Scholarships, one of which will be in Natural Science. Particulars can be had on application to the senior tutor. At the same time there will be an election at Magdalen College to not less than four Demyships and one Exhibition. Of the Demyships, one at least will be Mathematical, and one at least in Natural Science; the Exhibition will be in Mathematics. The stipend of the Demyships is 95*l.* per annum, and of the Exhibition 75*l.*, tenable for five years. For particulars apply to the senior tutor.

THE Board of Trade have been informed by the Meteorological Committee that they are now prepared to re-introduce the use of Admiral Fitzroy's signals (cones and drum) with slightly modified significations, and that the change will take effect on and after March 15, 1874. The signals to be used will consist of:—1°. Cone, point downwards for southerly gales: S.E. round by S. to N.W. 2°. Cone, point upwards for northerly gales: N.W. round by N. to S.E. 3°. Drum *with cone*, to indicate the probable approach of a *very heavy gale* from the direction indicated by the cone. The drum will not be used without the cone. The signals are to be kept hoisted *during the daylight only*, until 48 hours have elapsed from the time *the telegram was despatched*, unless countermanded. At night lanterns may be used wherever the local authorities deem it advisable to do so, as pointed out in an explanatory pamphlet, copies of which are supplied for gratuitous distribution. It will be seen from the pamphlet in question, that the meaning of the signals is that an atmospherical disturbance exists (which will be explained in the telegram) and will probably, but not *necessarily*, cause a gale at the place warned *from the direction* indicated by the signal. The Meteorological Office will supply the canvas shapes and lanterns to such places as require them, on loan; but in all cases the local authorities must undertake the charges incidental to the hoisting of the signal, such as flagstaff and gear, oil, &c., and also to the keeping of the apparatus in repair, painting, &c.

M. G. TISSANDIER, the editor of *La Nature*, is completing a series of observations for calculating the amount of atmospheric dust falling each day. The mean found is said to be several pounds in twelve hours for a surface not larger than the Champ de Mars, rather less than a half a square mile.

THIRTY-SEVEN small planets have been discovered in the years 1872 and 1873, or 18½ for each year, making 1,850 per century. From the days of Hipparchus to the present time we may reckon 2,000 years; had astronomers worked with the same zeal and success during these 2,000 years, the number of small planets known would have amounted to 37,000, only three times the number given by Arago of stars up to the 7th magnitude, and a very small proportion of the stars of the 10th magnitude. Although very minute, the latter are generally much brighter than small planets as seen at the time of opposition.

PROF. O. C. MARSH has made out some interesting points in connection with the remains of equine forms in the North American tertiaries. Following up the genealogy of the horse, as traced by Prof. Huxley in the European remains, he has been able to show that the American deposits present even a more complete series of intermediate forms. Between *Orohippus agilis* of the Eocene, which was about the size of a fox, and had four toes on the fore foot, with three behind, and *Equus fraternus* of the Pleistocene, which is not osteologically distinguishable from the existing *Equus caballus*, the following genera form the connecting links in form, size, and antiquity, viz. *Miohippus* and *Anchitherium* of the Miocene, and *Anchippus*, *Hipparion*, *Protohippus* and *Pliohippus* of the Pliocene. "Considering the remarkable development of the group through the entire Tertiary period, and its existence even later, it seems very strange that none of the species should have survived, and that we are indebted for our present horse to the old world."

IN continuation of his exquisite researches on the phenomenon of flight (*Comptes Rendus*, January 12, 1874), M. Marey has made a series of observations which prove how important a part the onward movement of a bird plays in increasing the efficiency of each wing stroke. For supposing that in its descent the wing did not continually come in contact with a fresh volume of air, it would act at a disadvantage, because the downward impulse which, at the commencement of each stroke, it gives to the air below it, would make that air so much less efficient a resisting medium; whilst, by continually coming in contact with a fresh body of air, the wing is always acting on it to the best advantage. For this reason, when a bird commences its flight, it turns towards the wind if possible, to make up for its lack of motion on starting.

THE extension of the Cinchona cultivation in Darjeeling continues. Every year additional land is brought under Cinchona culture, and it is calculated that 2,000 acres more will be cleared and planted within the next four years. With regard to Ipecacuanha, upwards of 20,000 plants and cuttings are now in hand, all of which promise well. Another interesting fact relating to the introduction of useful plants into India, is that of the success in the Terai of the Cacao (*Theobroma cacao* L.). The plants that were planted out about a year ago, were sent from Kew at the suggestion of Dr. Hooker, and they are now in a most healthy and satisfactory condition.

THE French Academy has at last published the list of candidates for the seat rendered vacant by the death of the late Dr. Nelaton. The issue is quite uncertain. M. Broca, the celebrated anatomist, has obtained only a second rank, and M. Marey is placed in the third.

FATHER SECCHI is preparing, at Gauthier Villars, a second edition of his work on the Sun, on an enlarged scale. He has quoted so largely from Mr. Lockyer's "Solar Physics" that an intended translation of this work is abandoned for the present.

QUITE a sensation was produced in the last sitting of the Academie des Sciences, by the exhibition of photographs of Spitzbergen scenery, sent by Prof. Nordenskiöld. One of these represented a meteorite nearly 18 tons in weight.

A BELGIAN paper describes an immense petrified trunk of a conifer discovered in the province of Lineburg in perfect preservation. Its length is about 33 feet, and its diameter about 20 inches.

THE *Annuaire* of the Bureau des longitudes for 1874 has been recently published. Although sold at 1½ fr., it contains chromolithographs showing solar protuberances, and an essay by M. Faye on questions relating to the sun.

THE widow of General Poncelet, one of the most distinguished French military engineers, has written to the French Institute, announcing that the whole of the works of her late husband will soon be in the hands of the public. The last volume, the sixth of the series, containing the lectures delivered at the Metz School of Artillery and the École Polytechnique, will be issued shortly. It is edited by M. Krœtz, Chief Engineer of the National Manufactures, one of the General's pupils. General Poncelet was a member of the French Institute for more than twenty years. He died in 1864.

A MEMOIR upon the embryology of *Terebratulina*, by Prof. Morse, has just been published by the Boston (U.S.) Society of Natural History, this being the result of a thorough investigation in regard to the development of this genus of the brachiopod shells found so abundantly on the coast of Maine. Prof. Morse's labours were mainly prosecuted at Eastport, and extended through a period of several years. He found that the species spawns throughout the entire summer season (at least from April to August), but that investigations in the earlier part of the season were preferable, since, with the increasing warmth, the development is more rapid than is convenient to the observer.

THE "Fenland Meteorological Circular and Weather Report" is the name of a monthly periodical, two numbers of which, for February and March, have just reached us. It is edited by Mr. S. H. Miller, F.R.A.S. The circular is intended to be "a medium for local meteorologists, an abiding record of the climate of the Fenland, and a register of the changes of the weather, to which the agriculturist, horticulturist, and naturalist may easily refer." It is intended besides, we believe, that the "Circular" should fill to some extent an educational function, and induce agriculturists to take an interest in the sciences with which their art is so intimately connected. This purpose is to be served by the publication of readable articles on scientific subjects, the first of which is by Mr. S. B. J. Skertchly, F.G.S., on the "Practical Bearings of Meteorology." The two numbers sent us contain well-constructed tabular and graphic reports of the meteorology of Wisbech for January and February, besides district reports, and a number of notes and short articles on subjects more or less intimately connected with the department to which the "Circular" belongs; the paper and typography are all that can be desired, and the price is only 2*d*. per month. The enterprise is highly creditable to its originators, and we sincerely hope it will be a great success and attain a wide circulation in the important district for whose benefit it has been started; and we hope the example thus set will be followed by other districts in the kingdom. The publishers of the "Circular" are Leach and Son, Wisbech.

A BILL has been introduced into the U.S. Congress proposing an appropriation of 7,000 dols. to enable the Department of Agriculture to make a collection of all the species of trees growing throughout the United States, and for their exhibition in suitable cases. The collection itself, when completed, is to be exhibited at the Philadelphia Centennial Exposition, but to belong to the Agricultural Department, and to be returned to it.

AT the meeting of the French Academy of March 2, M. Charles Sainte-Claire Deville, gave an account of his meteorological mission to Biskra and Tuggurt. At each of these stations an observatory has been established similar to that at Montsouris. Captain Roget superintends the observatory of Biskra, and Dr. Audet that of Tuggurt; the latter, according to M. Deville, is in an almost perfect situation, surrounded by a sufficient quantity of vegetation, and preserved from the effects of radiation. The results comprehend already observations continued during the month of January, and M. Deville sees in them the promise of important discoveries.

WE have received a useful work lately published by the Smithsonian Institution, prepared by Prof. F. W. Clark, of Howard University, Washington. This is the first part of a series entitled the "Constants of Nature," and gives in tabular form the specific gravities, the boiling and melting points, and the chemical formulæ of a large number of substances, with indications of the authorities whence the facts are derived. The volume contains about 250 pages, and is well provided with the necessary indices.

LIEUTENANT G. M. WHEELER (United States Engineers) and party are in Washington, and are engaged in elaborating the results of their explorations in 1873. Already about 76,000 square miles of territory have been carefully gone over and topographed with a view to their representation in the new series of index maps now nearly ready for publication. Much valuable information in regard to the geology of the country, its mining facilities, and the probabilities of successful irrigation, has been obtained, and will be duly published. In the line of natural history the collections have been very large, embracing at least 1,200 skins of birds, besides many hundreds of reptiles, fish, insects, &c. The botanical collection is said to be the finest and largest ever procured by a Government expedition. The results of the work of the expedition for the years 1871, 1872, and 1873 are, we understand, shortly to be published, comprising seven large quarto volumes, which will prove a valuable addition to the scientific history of the great West.

WE are glad to see, from Part IV. of the Transactions of the Clifton College Scientific Society, that that Society is exceedingly prosperous, so far as number and attendance of members is concerned, though we very much regret to learn that, like not a few other similar Societies, it contains but a small number of real workers. We hope that the patrons and office-bearers of the Society will do their best to devise some means to remedy this very serious defect, for serious the defect is, seeing that one of the main objects of such a Society is to train its members to methodical work, careful observation, and independent thinking. The only paper in this part, by a student member of the Society, is a long and elaborate one on Potteries, by C. C. Stevenson.

A THICK supplementary number of Petermann's *Mittheilungen* has been published containing a vast number of statistics relating to the population of the globe, with two excellent illustrative maps.

AT the meeting of the Adelaide Philosophical Society held on Nov. 25, 1873, Dr. Schomburgk read the second part of a long paper on poisonous plants. The plants noticed were those of the genus *Strychnos nux vomica*, *Datura stramonium* (the thorn-apple), *Solanum nigrum*, and *Taxus baccata* (the yew tree).

ACCORDING to the "Report of the Mining Surveyors and Registrars" of Victoria for the quarter ending September 30, 1873, the total yield of gold from alluvium and quartz reefs during the quarter was 291,861 ozs. 7 dwts. Appended to the Report is the continuation of Baron von Müller's description of New Vegetable Fossils of Victoria; the following are described and illustrated :—*Odontocaryon magregorii*, *Conchotheca rotundata*, and *Phytidotheca pleioclinis*.

THE additions to the Zoological Society's Gardens during the past week include a Finsch's Amazon (*Chrysotis finschi*) from W. Mexico, presented by Mr. C. Chivers; a Virginian Deer (*Cervus virginianus*) from N. America, presented by Mr. N. M. Bateson; a Cornish Chough (*Fregilus graculus*), British, presented by Mr. J. T. Hewes; a Common Otter (*Lutra vulgaris*), British, presented by Dr. Stafford; a Blue and Yellow Macaw (*Ara ararauna*) from S. America, presented by Miss J. Staines.

*THE GASEOUS, LIQUID, AND SOLID STATES OF WATER-SUBSTANCE**

IN two communications made by me to the British Association at its meetings at Edinburgh in 1871, and at Brighton in 1872, and printed as abstracts in the Transactions of the Sections for those years, considerations were adduced on relations between the gaseous, the liquid, and the solid states of matter. The new subject of the present paper constitutes a further development of some of those previous considerations, and a brief sketch of these is necessary here as an introduction for rendering intelligible what is to follow.

Taking into consideration any substance which we can have in the three states, gaseous, liquid, and solid, we may observe that when any two of these states are present in contact together, the pressure and temperature are dependent each on the other, so that when one is given the other is fixed. Then if we denote geometrically all possible points of temperature and pressure jointly by points spread continuously in a plane surface, each point in the plane being referred to two axes of rectangular co-ordinates, so that one of its ordinates shall represent the temperature and the other the pressure denoted by that point, we may notice that there will be three curves, one expressing the relation between temperature and pressure for gas with liquid, another expressing that for gas with solid, and another expressing that for liquid with solid. These three curves, it appears, must all meet or cross each other in one point of pressure and temperature jointly, which may be called the triple-point. The triple-point, considered in respect to its temperature, is in fact what would often be called the freezing point *in vacuo*; that is, the freezing temperature of water in contact with no gas except its own aqueous vapour or steam; and the pressure at the triple point is just the pressure of that aqueous gas or steam.

The curve between gas and liquid, which may be called the *boiling-line*, will be a separating boundary between the regions of the plane corresponding to the ordinary liquid and those corresponding to the ordinary gaseous state. But by consideration of Dr. Andrews's experimental results ("Phil. Trans.," 1869) we may see that this separating boundary comes to an end at a point of temperature and pressure which, in conformity with his language, may be called the *critical point* of pressure and temperature jointly; and we may see that, from any liquid state to any gaseous state, the transition may be gradually effected by an infinite variety of courses passing round the extreme end of the boiling-line.

The accompanying figure serves to illustrate these considerations in reference to transitions between the three states, the gaseous, the liquid, and the solid. The figure is intended only as a sketch to illustrate principles, and is not drawn according to measurements for any particular substance, though the main features of the curves shown in it are meant to relate in a general way to the substance of water, steam, and ice. A X and A Y are the axes of coordinates for the temperatures and pressures respectively; A, the origin, being taken as the zero for pressures and as the zero for temperatures on the Centigrade scale. The curve L represents the *boiling-line* terminating in the critical point E. The line T M represents the line between liquid and solid. It is drawn showing in an exaggerated degree the lowering of the freezing temperature of water by pressure; the exaggeration being necessary to allow small changes of temperature to be perceptible in the diagram. The line T N represents the line between the gaseous and the solid states of water-substance. The line L T N appears to have been generally (in the discussion of experimental results on the pressure of aqueous vapour above and below the freezing-point) regarded as one continuous curve; but it was part of my object in the two British-Association papers referred to, to show that it ought to be considered as two distinct curves (L T P and N T Q) crossing each other in the triple-point T.

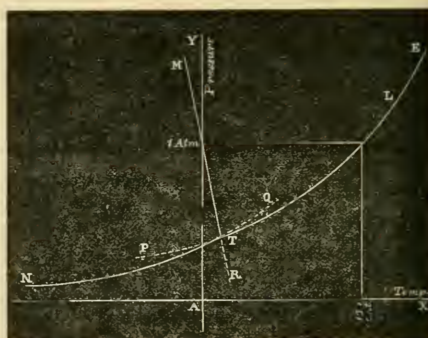
In the second of the two British-Association papers already referred to (the one read at the Brighton meeting, 1872), I gave demonstrations showing that these two curves L T and N T should meet, as shown in the accompanying figure, with a re-entrant angle at T, not with a salient angle such as is exemplified in the vertex of a pointed arch; and offered in conclusion the suggestion that the reasoning which had been adduced might be followed up by a quantitative calculation founded on experimental data, by which calculation the difference of the pressures of steam with water, and steam with ice for any given temperature very near the triple point, may be found with a very close approximation to the truth.

In the month of October 1872 I explained to my brother, Sir William Thomson, the nature of that contemplated quantitative calculation: I mentioned to him the method which I had prepared for carrying out the intended investigation, and inquired of him for some of the experimental data, or data already deduced by theory from experiments, which I was seeking to obtain. On his attention being thus turned to the matter, he noticed that the desired quantitative relation could be obtained very directly and easily from a simple formula which he had given in his paper on the Dynamical Theory of Heat, "Transactions of the Royal Society of Edinburgh," March 17, 1851, § 21 (3), to express the second law of thermodynamics for a body of uniform temperature throughout, exposed to pressure equal in all directions.

That formula is

$$\frac{dp}{dt} = C\,M$$

in which p denotes the amount of the pressure, and $\frac{dp}{dt}$ its rate of increase per unit increase of temperature, the volume being kept constant; C denotes Carnot's function; and M denotes the rate of absorption at which heat must be supplied to



the substance per unit augmentation of volume, to let it expand without varying in temperature. The body may be either homogeneous throughout, as a continuous solid, or liquid, or gas; or it may be heterogeneous, as a mass of water and aqueous vapour (*i.e.* steam), or ice and water, or ice and aqueous vapour (*i.e.* steam).

Now apply that formula, 1st, to steam with water, and 2nd, to steam with ice, the temperature of the heterogeneous body in each case being that of the triple-point, or we may for the present purpose say 0° C., which is almost exactly the same. It is to be observed that while in the general application of the formula the rate of increase of the pressure with increase of temperature, *when the volume is kept constant*, has been denoted by $\frac{dp}{dt}$, yet in each of the two particular cases now brought under consideration it is a matter of indifference whether the volume be kept constant or not; because the pressure of steam in contact either with water or with ice, for any given temperature, is independent of the volume of the whole heterogeneous body; so that the change of pressure for change of temperature is independent of whether there be change of volume or not. As C is a function of the temperature which has the same value for all substances at the same temperature, it has the same value for the two cases now under consideration. Hence, retaining for the first case (that, namely, of steam with water) the same notation as before, but modifying it by the use of an accent where distinction is necessary in the second case (that of steam with ice), and thus using $\frac{dp}{dt}$ to denote the rate of increase of the pressure per unit increase of temperature for steam with wate

* "A Quantitative Investigation of certain Relations between the Gaseous, the Liquid, and the Solid States of Water-Substance." By Prof. James Thomson, LL.D., lately of Queen's College, Belfast, now of the University of Glasgow. Communicated to the Royal Society by Sir William Thomson, LL.D., F.R.S. Abridged for NATURE by the Author.

at the triple-point (0° C. nearly), and M to denote the rate of absorption at which heat must be supplied to a body consisting of steam and water at the triple point, per unit augmentation of volume of that whole heterogeneous body, to let it expand without varying in temperature, and using $\frac{dp'}{dt}$ and M′ to denote the corresponding rates for steam with ice at the triple point, we have

$$\frac{\frac{dp}{dt}}{\frac{dp'}{dt}} = \frac{M}{M'}$$

The latent heat of evaporation of one pound of water at the freezing-point (or at the triple point) into steam at the same temperature, as determined by Regnault, is 606·5 thermic units, the thermic unit being here taken as the heat which would raise the temperature of 1 lb. of water 1° C., and the latent heat of fusion of ice is about 78 or 79 of the same thermic units. Hence, though M and M′ belong each to a cubic foot of steam at the triple point, not to a pound mass of it, still the ratio $\frac{M}{M'}$, is = $\frac{606}{79 + 606}$

Hence

$$\frac{\frac{dp}{dt}}{\frac{dp'}{dt}} = \frac{606}{79 + 606} = \frac{1}{1 \cdot 13}$$

This shows that for any small descent in temperature from the triple point (where the pressure of steam with ice is the same as that of steam with water), the pressure of steam with ice falls off 1·13 times as much as does the pressure of steam with water.

In submitting the quantitative calculation now given, I have preferred to adopt the method proposed and developed by my brother rather than that which I had myself previously devised, because his method is simpler, and brings out the results more briefly by established principles from existing experimental data. I may say, however, that the method devised by myself was also a true method, and that I have since worked it out to its numerical results, and have found that these are quite in accordance with those brought out by my brother. The two indeed may be regarded as being essentially of the same nature; and I think it unnecessary to occupy space by giving any details of the method I planned and have carried out. Its general character may be sufficiently gathered from the concluding passages of the British Association 1872 paper, as printed in the Transactions of the Sections, Brighton Meeting.

In order to discover whether the feature now developed by theoretical considerations is to be found showing itself in any degree in the experimental results of Regnault on the pressures of steam at different temperatures *, I have made careful examinations of his engraved curve (Plate viii. of his Memoir), and of his empirical formulæ adapted to fit very closely to the results exhibited in that curve, and of his final tables of results at the close of his Memoir; and by every mode of scrutiny which I have brought to bear on the subject—in fact by each of some seven or eight varied modes—I have met with clear indication of the existence of the expected feature; and by some of them I have found that it can readily be brought prominently into notice. The engraved curve drawn on the copperplate by Regnault himself is offered by him as the definitive expression of his experiments, as being an expression which satisfies as well as possible the aggregate of his observations; subject, however, to a very slight alteration, which he has pointed out as a requisite amendment in the part of the curve immediately below the freezing-point, a part with which the investigations in the present paper are specially concerned.

After telling (p. 581 of his Memoir) of the great care with which he had marked the curve on the copperplate and got it engraved, he says:—"Je n'ai pas pu éviter cependant quelques petites irrégularités dans les courbes; mais une seule de ces irrégularités me paraît assez importante pour devoir être signalée. Elle se présente pour les basses températures comprises entre 0° et − 16°, la courbe creuse trop vers l'axe des températures, elle laisse, notablement au-dessus d'elle, toutes les déterminations expérimentales qui ont été faites entre 0° et − 10°. Ainsi les valeurs, que cette petite portion de la courbe donne pour les forces élastiques, sont un peu trop faibles, et j'ai eu soin de les augmenter, de la quantité convenable, dans les nombres que je donnerai plus loin." Whether we are now to think that this bend downwards* of the curve towards the axis of temperatures involving what Regnault regarded as a small faulty departure of his drawn curve from his actual experiments, was introduced merely by a casual want of accuracy in drawing, or whether we may suppose that possibly there may have been some experimental observations which attracted the curve downwards, but were afterwards rejected on a supposition of their being untrustworthy, it appears that such a bend is a feature which the curve really ought to possess, and is one which, even after being partially smoothed off by way of correction, is not obliterated, but still remains clearly discoverable in the final numerical tables of results.

This is best brought to light by means of the empirical formulæ devised and employed by Regnault for the collating of his results. He proceeded evidently under the idea of the curve being continuous in its nature, so that a single formula might represent the pressures of aqueous vapour throughout the whole of his experiments; but before seeking for such a formula he proceeded to calculate several local formulæ of which each should represent very exactly his experiments between limits of temperature not wide apart; and afterwards he worked out several general formulæ, each adapted singly for the whole range of his experiments.

Now in the paper communicated to the Royal Society, and printed in the Proceedings for December 11, 1873, from which the present paper is an abridgment, the details of a scrutiny of the chief of these formulæ are given (the formulæ, especially, which were adopted by Regnault for deducing his final general table extending from − 32° C. to + 230° C.), from which it appears that they present clear indications that at and very close to the freezing-point (or rather the triple-point) the rate of increase of pressure for increase of temperature is decidedly less in the case of steam with water than in that of steam with ice; or, in other words, that at and very close to the triple-point the steepness of the curve for steam with water is decidedly less than that of the curve for steam with ice; or, to state the same a little more fully, that while the steepness is increasing as we ascend from temperatures below the triple-point up to the triple-point, with ice in contact with steam, there is a sudden abatement of the steepness in passing the triple-point, where the change occurs from steam with ice to steam with water, after which, with continued rise of temperature, the steepness goes on again increasing. In fact the result comes out that these formulæ, expressing an aggregate of experimental results of Regnault, would indicate for $\frac{\frac{dp}{dt}}{\frac{dp'}{dt}}$ at the freezing-point, or the triple-point, not the value 1 (as would be the case if a curve continuous past the triple-point would express the pressure of steam or aqueous vapour, for different temperatures, in contact with ice below the triple-point and with water above it), but 1·09 or 1·10, which makes a near approach to the result 1·13 found by my brother's quantitative calculation already here cited. The decimal fractions in excess of unity, here represent the quantitative relation between the greatness of the feature under consideration as brought out by the theoretical investigation on the one hand, and as deduced from Regnault's results on the other hand: and thus we may say that this feature can be brought to view as existing in Regnault's principal results in a degree about $\frac{9}{13}$ or $\frac{10}{13}$ of that in which the theoretical investigation shows that it must really exist, and ought to be found experimentally, if the experiments had a sufficiently minute exactitude to detect it and to measure it.

Regnault also gives, in the same Memoir, another statement of results deduced from his experiments, and put in the form of a table intended chiefly for meteorological purposes; which table shows the pressures of aqueous vapour for temperatures ranging below and above the freezing-point at very small intervals of temperature, $\frac{1}{10}$th of a degree centigrade each. In this table, the numbers inserted as representing the pressures below the freezing-point are slightly different from the corresponding ones in his general table, which, with the formulæ used in making it, has just now been referred to; and he mentions that this slight

* Regnault, "Des forces elastiques de la vapeur d'eau aux différentes températures," Mémoires de l'Académie des Sciences, 1847.

* In M. Regnault's curve the temperatures are measured horizontally across the sheet and pressures are measured upwards.

discrepance has resulted from the fact that the two tables were formed at different periods, and were not calculated by the same formula; but he remarks that the differences are insignificant, as they scarcely amount to ·02 millimetre of mercury in the pressures which the two tables respectively show. Here, too, as in the general table, the feature expected shows itself, though in a diminished degree. By careful examination of the minute changes of pressure for small changes of temperature, close to the freezing-point, both above and below it, as they are shown in this table, I find that the experimental results as here offered would indicate the existence of the feature in a degree about $\frac{5}{13}$ or $\frac{6}{13}$ of that in which the theoretical investigation now shows that it ought to be met with, if experiments could be made on pressures of aqueous vapour, above and below the freezing-point, with sufficiently minute exactitude.

It is indeed a great credit to the accuracy of Regnault's experiments, and to the exactitude of his results, that the results contain the clear indications they do of this feature, which only comes to view through comparison of differences of pressure represented by very minute fractions of a millimetre of mercury; and which, unless a very high order of accuracy were maintained, might have given no perceptible indication of its existence, or might readily have been made to disappear totally from the final results, through the application of the ordinary methods for clearing off small errors of observation.

SCIENTIFIC SERIALS

American Journal of Science and Arts, February 1874.—This number commences with a paper by Mr. Langley (accompanied with plate), describing studies on the minute structure of the solar photosphere, made at the Alleghany Observatory. The equatorial used had an aperture of 13 inches. The author finds that the ultimate visible constituents of the photosphere are not the "rice grains," but small *granules* composing them, and not more than 0″·3 in size. Comparing the total area covered by them with that of the whole sun, he estimates that the greater part of the solar light comes from an area of not over one-fifth of its visible surface, and which may be indefinitely less. Hence the received estimates of the intensity of the action to which solar light is due must, he thinks, be greatly increased. In the penumbra there are not only numerous small cyclones, and even right- and left-handed whirls in the same spot, but probably currents ascending nearly vertically. The action of superposed approximately horizontal currents is a prominent feature. The outer penumbral edge seems to be formed by rupture. Mr. Langley accepts M. Faye's theory as the most probable.—Prof. Pickering communicates some measurements of the polarisation of light reflected by the sky, and by one or more plates of glass. One remarkable result arrived at was, that the polarisation (from the sky) is the same, for a given solar distance, for any meridian distance; in other words, that the polarisation is the same for all points equally distant from the sun.—In a translated paper on the dissipation of electricity in gases, by a Russian physicist, M. Boboulieff, the author concludes from his experiments, that the dissipation in air (and other gases) diminishes with diminution of the pressure; and that the dissipation in hydrogen is less than in air (at the same pressure).—Mr. Verrill continues his notes on results of recent dredging expeditions on the coast of New England.—In the "Scientific Intelligence" we find a summary of a recent important memoir by Prof. Morse on the systematic position of the Brachiopoda. His avowed object is to show that in every point of their structure the Brachiopoda are true worms, with possibly some affinities to the Crustacea, and that they have no relations to the Mollusca, save what many other worms may possess in common with them.—The organisation of an American Metrological Society is announced; the design being to originate and promote measures for improving the system of weights, measures, and moneys, and bring these into relations of simple commensurability with each other.

In the number of the *Bulletin Mensuel de la Société d'Acclimatation de Paris* issued in January one of the principal papers is an article by M. Mérice on Agriculture in Brazil. This country is by nature fitted to be one of the most prolific agricultural tracts of earth in the world, so varied and abundant are its productions, and so fruitful its soil. Improved implements are necessary, and increased skill would give greatly increased results. Great strides are being taken in the "education" of various kinds of silkworms, and under the directions given in the *Bulletin* the different varieties may be properly reared on the most approved principles.—M. Carbonnier, to whom the honour is due of introducing the "Paradise fish" from China, has been successful in importing some live specimens of another species of *Macropodus*, the "rainbow-fish" of India: specimens of the *Pesca-re*, or "king-fish" of South America have also been brought to Paris from Buenos Ayres. M. E. Perris' paper on birds and insects is continued.—The recent transmission of salmon ova to New Zealand, the cultivation of lobsters in the United States, the introduction of the *Eucalyptus* in various parts of Europe, are all, amid a mass of other matter, referred to at length. The number for January, just received, gives an interesting account of the year's work at the *Jardin d'Acclimatation.* In the Bois de Boulogne experiments have been made in the cultivation of various vegetables and other useful plants, on the results of which the future utilisation of new importations greatly depends.—The notes on the cultivation of the vine and on the use of mineral manures will be found very valuable.—The question of fish culture, which has assumed such large proportions in England and America, is being taken up by the Society, and an interesting paper on the subject is contributed by M. de la Blancheu.

Reale Istituto Lombardo di Scienze e Lettere. Rendiconti: Dec. 18, 173. In this number Prof. Lombroso furnishes exact measurements of the crania of 66 Italian criminals (from various museum collections) along with an interesting analysis of those data. With reference to capacity as measured by apparent circumference, while there were a few of pretty large circumference (1 of 580, 1 of 550, 2 of 560, 2 of 540, out of 65), and a moderate number of ordinary size (8 of 530, 13 of 520), a large proportion were quasi-microcephalic (39 out of 65); and precisely 19 of 510, 8 of 490, and 12 of 500. Of 40 crania examined the mean capacity, in cubic centimetres, was 1,389; two were of more than ordinary capacity (1,610 and 1,633), 3 were of ordinary (1,500 and more), 12 had a capacity of 1,400 and more, 19 were of much inferior capacity (1,300 and more), while 4 were truly microcephalic, with a capacity of 1,100 to 1,200. Of the last, 2 were crania of assassins, 1 that of a thief, and 1 that of an incendiary (with intent to rob). Prof. Cantoni gives the concluding portion of a valuable paper in experimental physics, on the polarisation of non-conductors. He here takes up several objections urged by Prof. Righi to his opinion as to the possibility of polarising a non-conductor durably.—M. Corradi continues an historical sketch of the study and teaching of anatomy in Italy in the Middle Ages.—We also note short papers on primitive tumours of the dura mater (by M. Bizzozero), and on a remarkable appearance of the zodiacal light, and a shower of falling stars observed in some parts of Italy on December 12 last.

Bulletin de l'Academie Royale des Sciences (*de Belgique*). No. 12. In this number are given a series of papers or lectures of a somewhat popular nature, read at the public seance in December. The first is by M. Gluge, who advocates the teaching of biology in the Belgian schools.—M. d'Omalius d'Halloy follows with an argument for the hypothesis of transformation by generations of forms from a first creation, as against that of successive creations on the one hand, and that of evolution from matter on the other.—The next lecture, by M. van Beneden, is entitled "A Word on the Social Life of the Inferior Animals," and gives some curious facts in natural history, relating especially to parasites.—And lastly, we have an able lecture by M. Schwann, on the commencement and the end of the world, according to the mechanical theory of heat. The author gives a lucid exposition of the two fundamental principles of conservation and dissipation of energy, explaining, with special fulness, the doctrine enunciated by Clausius and the considerations leading to it.—The *Bulletin* further contains reports by members of the Academy on various prize-competitions. One subject proposed was the relation of heat to development of phanerogamic plants, with special reference to the periodic phenomena of vegetation. The Committee give lengthy analyses of the memoir received, to which, while of some scientific merit, the prize is not awarded. In a lecture by M. Morren on the subject, the law is elucidated, that, other things being equal, the quantity of carbon fixed by a vegetation is greater in proportion as its height is less, inasmuch as this supposes a less expenditure of movement.—Another question called for a description of the coal system of the Liége Valley. From a memoir on which the committee report favourably, it appears that instead of having twenty-five beds of coal, as had been thought since the labours

of Dumont, the district referred to contains scarcely half that number.—Several mathematical notes are given, and there is a description of three additions to the synopsis of Calopterygines, by M. Longchamps.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 12.—"Contributions to the Developmental History of the Mollusca, Sections I., II., III., IV." By E. Ray Lankester, M.A., Fellow of Exeter College, Oxford. Communicated by G. Rolleston, F.R.S., Linacre Professor of Anatomy and Physiology in the University of Oxford.

The points of greatest interest to which the author draws attention in the present memoir are :—

1. The explanation of the basket-work structure of the surface of the ovarian egg, by the plication of the inner egg-capsule.
2. The increase of the yelk by the inception of cells proliferated from the inner egg-capsule.
3. The homogeneous condition of the egg at fertilisation.
4. The limitation of yelk-cleavage to the cleavage-patch.
5. The occurrence of independently-formed corpuscles (the autoplasts) which take part in the formation of the blastoderm.
6. The primitive eye-chamber formed by the rising up of an oval wall, and its growing together so as to form a roof to the chamber.
7. The origin of the otocysts by invagination.
8. The rythmic contractility of a part of the wall of the yelk-sac.
9. The disappearance of the primitive mouth, and the development of a secondary mouth.
10. The development of a pair of large nerve-ganglia by invagination of the epiblast immediately below the primitive eye-chambers.

"The Localisation of Function in the Brain," by David Ferrier, M.A., M.R.C.P., Professor of Forensic Medicine, King's College, London. Communicated by J. Burdon Sanderson, F.R.S., Professor of Practical Physiology in University College.

The chief contents of this paper are the results of an experimental investigation tending to prove that there is a localisation of function in special regions of the cerebral hemispheres.

Anthropological Institute, March 10.—Prof. George Busk, F.R.S., president, in the chair. A paper, by Dr. A. P. Reid, was read, "On the mixed or half-breed Races of North-Western Canada." The mixed races were nine in number, viz. the progeny of (1) the Anglo-Saxon father and Indian mother, (2) the French and French-Canadian father and Indian mother, (3) the Anglo-Saxon father and mixed Anglo-Saxon and Indian mother, (4) the French father and mixed French and Indian mother, (5) the "half-breed" Anglo-Saxon and Indian as father and mother, (6) the "half-breed" French and Indian as father and mother, (7) the descendants proceeding from intermarriage of 5th class, (8) the descendants proceeding from intermarriage of 6th class, (9) the mixed or "half-breed" father and Indian mother. Those nine divisions included the principal mass of the mixed peoples of Manitoba. The French and Anglo-Saxons and their descendants rarely intermarried. The author pointed out the marked change in physique, which was common to all the classes he had enumerated, that quickly followed the removal of Europeans to American soil. The complexion becomes swarthier and more nearly resembling the type of native Americans than one would suppose. That change was due to climatic influences, to different food, and to altered customs. On the whole, there was a tendency, in all the mixed races, to the Indian rather than to the European type. They could not be said to possess any objectionable peculiarities; they were not more inclined to the abuse of alcohol or to other irregularities than the pure whites; and it would be difficult to find a people who have fewer faults. Some of the families of the pure white and pure Indian were often very numerous, sometimes reaching the number of fifteen; but four to six was the average.—A paper, by the Rev. George Taplin was read, "On the mixed races of Australia and their migrations." The author's deductions were made chiefly from linguistic data. He however recorded the fact of having met with some individuals of the Narrinyeri tribe who had light complexions and straight hair. He found also that among the Narrinyeri there were superstitions and customs identical, even in name, with those obtaining among the Samoans.—Commander Telfer, R.N., communicated notes on the discovery of burial grounds near Tiflis in Georgia. In one of the graves were found parts of a body that had undoubtedly been interred in a sitting posture. The skull of an adult was remarkably distorted, and bore a striking resemblance to the longest form of the Titicacan skulls of South America.—A paper by Miss A. W. Buckland "On the Serpent, in connection with primitive metallurgy," was also read.

Royal Horticultural Society, March 4.—General Meeting. —Lieut.-Gen. Hon. Sir A. H. Gordon, K.C.B., in the chair.— The Rev. M. J. Berkeley commented on some of the plants shown. They included *Encholirion corallinum*, a curious Bromeliaceous plant from Brazil, a fine species of Medinilla probably new, and the beautiful *Iris reticulata*, which, though a native of Persia, proved quite hardy in this country.

Scientific Committee.—Dr. Hooker, C.B., P.R.S., in the chair.—The Rev. M. J. Berkeley called attention to the following communication made by Prof. Panceri to the Institut Egyptien at its meeting on December 13, on Cryptogamic vegetation found within the egg of an ostrich, which was interesting in connection with what he had himself brought before the committee on March 5 and 19, 1873. The egg had been given Prof. Panceri at Cairo, and was still fresh, the air space having not even been formed. He soon, however, noticed the appearance of dark blotches within the shell, and having broken it open to ascertain the cause, he found that they were produced by the growth of minute fungi. Instances of a similar kind had already been studied by him, and he had communicated the results to the Botanical Congress held at Lugano in 1859. The Rev. M. J. Berkeley had found *Cladosporium herbarum* in the interior of a fowl's egg.— Dr. Masters brought shoots of *Picea nobilis*, in which the primary shoot was dead and swollen beneath the apex. In many instances he had found similar excrescences to contain the larva of an insect. In other cases the primary cause of injury appeared to be frost or cutting east winds.—Dr. Masters exhibited some peas which had been attacked by a beetle (*Bruchus pisi*) which fed on the cotyledonary portion, but left the plumule, so that the seeds still germinated.—Dr. Masters reported on the monstrous Cyclamen which had been referred to him at the last meeting. The apparent corolline whorl in the Primulaceæ is now regarded as an outgrowth from the andrœcium. In the present case there appeared to be a supplementary staminal whorl alternating with the normal one, and therefore with its members opposite to the sepals. These members, however, had become partially petaloid, and were rolled up, so that the whole flower had a superficial resemblance to a case of lateral prolification.—Mr. Grote stated that Mr. F. Moore, of the Indian Museum, agrees with Prof. Westwood, and refers the Assam Tea-bug to the genus *Helopeltis* of the Capsidæ. A Ceylon species of this bug is figured by Signoret in the *Ann. Soc. Entom. de France*, 3rd series, pl. 12, fig. 2. Two other species are known from the Indian Archipelago. The Indian species described by Mr. Peal, differs from the Ceylon species in its habit of feeding on the juice of the tea-plant; and Mr. Moore proposes to call it *H. theivora*.—Prof. Thiselton Dyer read the following extract from a letter from Mr. James Caldwell, Port Louis, Mauritius:—"I would specially call your attention to a case in which the ribbon cane has sported into a green cane and a red cane from the same head. I have at least 200 instances of it in the same plantation, and the fact has completely upset all our preconceived ideas of the difference of colour being permanent. The conversion of a striped cane into a green cane was not uncommon, but the change into a red cane universally disbelieved, and that both events should occur in the same plant incredible. I find, however, in Fleischman's 'Report on Sugar Cultivation in Louisiana for 1848,' published by the American Patent Office, the circumstance mentioned, but he says he never saw it himself."—In the report of the meeting for Feb. 11 (NATURE, vol. ix. p. 354) the word "gabsy" in line 12 should be omitted.

Mathematical Society, March 12.—Dr. Hirst, F.R.S., president, in the chair.—The following papers were read:—On certain constructions for bicircular quantics, and On a geometrical interpretation of the equations obtained by equating to zero the resultant and the discriminant of two binary quantics, by Prof. Cayley.—On the Cartesian equation of the circle which cuts three given circles at given angles, by J. Griffiths.—On another system of poristic equations, by Prof. Wolstenholme.

EDINBURGH

Royal Physical Society, Feb. 25.—Dr. John Alex. Smith, president, in the chair.—On a New Mode of Esti-

mating the Amount of Colour in Water, by Mr. J. Falconer King. Mr. King's process consists in adding to chemically pure water a standard coloured solution contained in an accurately graduated instrument until the pure water equals in colour the specimen of water under examination. The result of an estimation of colour in a water can thus be accurately recorded and preserved for future reference.—Occurrence of the Deal Fish (*Trachypterus arcticus*), near Montrose, by James C. Howden, M.D., Sunnyside.—Notes of the American Bittern (*Botaurus lentiginosus*), and some other of our rarer birds recently shot in the South of Scotland, by John Alex. Smith, M.D.—Note on a New Fossil from the Silurian Rocks in the Pentland Hills, by Mr. D. J. Brown. Mr. Brown described a section through the rocks in which the fossil occurred. The fossil he believed to be a seaweed, of which it appeared to be a frond. This is the third specimen of seaweed that has been found in these rocks.—Note on Bryozoa, from the carboniferous limestone at Longniddry Station, by Mr. D. J. Brown. Mr. Brown exhibited a fine series of Bryozoa from the lower carboniferous limestone group of Longniddry quarry, Haddingtonshire. This series of Bryozoa consisted principally of fragments of the genera *Fenestrella* and *Polypora*, the whole facies being eminently that of the carboniferous limestone, although amongst them was one fragment apparently referable to the Permian genus *Thamniscus*.—On some Peculiarities in the Geographical Distribution of the Mammalia of Greenland, as explanatory of the origin of the flora and fauna of that country, by Dr. Robert Brown, secretary. Dr. Brown considered that a great portion of the Greenland fauna and the bulk of its flora had been derived from Europe when Greenland was united, probably during or shortly after the time the Miocene beds were laid down to the European continent, by continuous land or a chain of islands, of which it is possible that Iceland, Bear Island, and perhaps even the Orkneys and Shetlands, are only fragments.

MANCHESTER

Literary and Philosophical Society, Feb. 24.—Rev. William Gaskell, vice-president, in the chair.—On the Effect of Acid on the Interior of Iron Wire, by Prof. Osborne Reynolds. It will be remembered that at a previous meeting of this Society Mr. Johnson exhibited some iron and steel wire in which he had observed some very singular effects produced by the action of sulphuric acid. In the first place the nature of the wire was changed in a marked manner, for although it was soft charcoal wire it had become short and brittle; the weight of the wire was increased; and what was the most remarkable effect of all was that when the wire was broken and the face of the fracture wetted with the mouth it frothed up as if the water had acted as a powerful acid. These effects, however, all passed off if the wire were allowed to remain exposed to the air for some days, and if it were warmed before the fire they passed off in a few hours. Prof. Reynolds subjected one of the pieces of wire to a farther examination, and from the result of that examination was led to what appears to be a complete explanation of the phenomena. He was led, from certain observations, to conclude that the effect was due to hydrogen, and not to acid, as Mr. Johnson appeared to think, having entered into combination with the iron during its immersion in the acid, which hydrogen gradually passed off when the iron was exposed. This conclusion he tested and proved to be correct by further experiments. The question appears to the author one of very considerable importance, both philosophically and in connection with the use of iron in the construction of ships and boilers. If, as is probable, the saturation of iron with hydrogen takes place whenever oxidation goes on in water, then the iron of boilers and ships may at times be changed in character and rendered brittle in the same manner as Mr. Johnson's wire, and this, whether it can be prevented or not, is at least an important point to know, and would repay a further investigation of the subject.—Dr. Ransome demonstrated the movements of the chest in respiration, showing the remarkable mobility of its several parts, and the consequent facility with which its cavity can be inflated.

BALTIMORE

Maryland Academy of Sciences, Feb. 2.—A paper was read from Prof. D. S. Martin upon the economical resources of Cornwall, embracing one of the most remarkble deposits of iron ore in America, and forming three large banks. Reference was made in the paper to the immense development of the magnetic oxide of iron in these mines, and to the fact that some of the ore exhibits marked magnetic polarity (native lode-stone). The yield is 175,000 tons annually, but the capacity is double. The minerals of unusual interest found here, with the magnetite, are lodes and coatings of cuprite, chrysocolla, azurite, malachite, and brochantite, the last named being found in no other locality in Eastern North America.

PARIS

Academy of Sciences, March 9.—M. Bertrand in the chair.—M. H. Resal communicated a paper on the theory of the "ground swell" (*houle*).—On a new spiral regulating chronometers and watches, by M. Phillips. The results of experiments made to test the isochronism of chronometers provided with the new spiral.—Researches on crystalline dissociation; estimation and division of the work done in saline solutions, by MM. P. A. Favre and C. A. Valson. A continuation of former communications on this subject.—On a particular arrangement of micrometer with movable wires proposed for the telescopes to be used for the observation of the Transit of Venus, by M. Ph. Hatt. Communicated by M. Fizeau.—New note on waves of variable height and velocity, by M. L. E. Bertin.—On the dispersion of gases, by M. Mascart. The author has determined the dispersion of air, nitrogen, hydrogen, N_2O, CO, CO_2, and CN. The dispersion of these gases bears no direct relation to their refractive power nor to their density.—On the wave-lengths and characters of the violet and ultra-violet rays of the solar spectrum, given by a photograph taken by means of a diffraction grating, by M. H. Draper. An abstract of this paper and the accompanying Alberttype print have already appeared in this journal.—Note on hydrogenised palladium, by MM. L. Troost and P. Hautefeuille. By studying the tension of the gas in the metal at various temperatures the authors come to the conclusion that hydrogenised palladium is a definite compound of hydrogen and palladium with an excess of hydrogen dissolved in it. The tension of the hydrogen is constant from the time the amount of contained gas is equal to 600 volumes; this amount corresponding to the formula Pa_2H. The authors announce a future communication on hydrides of potassium and sodium (K_2H and Na_2H). No allusion is made to the results recently obtained by Wright and Roberts by the determination of the specific heat of hydrogenised palladium.—New apparatus for determining the tannin contained in the different astringent materials employed in tanning, by M. A. Terreil. The process used depends upon the absorption of oxygen by tannin in presence of alkaline liquids.—Organogenesis compared with androgenesis in its relations with natural affinities (Classes *Selaginaceæ* and *Verbenaceæ*), by M. A. Chatin.—Reply to a reclammation of priority of M. Béchamp, by M. P. Schutzenberger.—Probable character of the first fortnight of March, by M. de Tastes. A weather prognostication.—Researches on the origin of the lithological elements of the tertiary and quaternary soils of the neighbourhood of Oran, by M. Daubrée. The author concludes from his researches that the Middle Tertiary epoch was especially an age of eruptions of a trachytic nature. M. A. Nordenskiöld presented to the Academy some photographs taken in Spitzbergen in 1872–73. Among the photographs was one of the largest known mass of meteoric iron. It was discovered in Greenland (Ovifak) in 1870. This mass weighs 21,000 kilogrs. and is about to be brought to Stockholm for the Royal Museum.

THURSDAY, MARCH 26, 1874

THE SCIENCE COMMISSION'S MUSEUM REPORT

THE Royal Commission on Scientific Instruction and the Advancement of Science have just issued their fourth Report, which is mainly concerned with the principal public Scientific Museums and Collections of the Metropolis, touching also briefly on the Scientific Museums and Botanic Gardens of Edinburgh and Dublin, and at some length upon provincial Local Museums generally, and upon the means by which these last might be made widely beneficial for scientific instruction. The Report also deals with the subject of Public Lectures in connection with Museums.

The Metropolitan Museums dealt with in the Report are the British Museum, the Museum of the Royal College of Surgeons, the National Botanical Collections and Gardens, the Museum of Practical Geology, and the South Kensington Museum, with its branch at Bethnal Green. The Report of the Commission is founded upon a thorough investigation into the growth and present condition of these institutions, and the opinions of a large number of men competent to speak on the subject as to the best means of systematising the various institutions, and of enabling them to discharge efficiently the objects for which they exist. The following are the principal recommendations of the Commissioners, which we prefer to give in the words of the Report.

With regard to the Natural History Collections of the British Museum, it is recommended :—

"That a Director be appointed by the Crown, and should have the entire administration of the establishment, under the control of a Minister of State, to whom he should be immediately responsible. That the appointments of keepers and other scientific officers should be made by the Minister, after communication with the Director and with the Board of Visitors.

"That a Board of Visitors be constituted, to be nominated in part by the Crown, in part by the Royal and certain other Scientific Societies of the metropolis, and, in the first instance, in part also by the Board of Trustees ; the members to be appointed for a limited period, but to be re-eligible ; and that the Board of Visitors should make annual reports to the Minister, to be laid before Parliament, on the condition, management, and requirements of the Museum, and should be empowered to give him advice on any points affecting its administration."

With regard to the National Botanical Collections and Gardens, the Commission recommend :—

"That the collections at the British Museum be maintained and arranged with special reference to the geographical distribution of plants and to palæontology ; and that the collections at Kew be maintained and arranged with special reference to systematic botany.

"That all collections of recent plants made by Government expeditions be, in the first instance, sent to Kew, to be there worked out and distributed, a set being reserved for the British Museum ; and that all collections of fossil plants made by Government expeditions be sent to the British Museum.

"That opportunities for the pursuit of investigations in physiological botany should be afforded in the Royal Gardens at Kew."

With regard to the Museum of the Royal College of Surgeons, it is recommended :—

"That, should the fund at the disposal of the College prove inadequate for the efficient maintenance and continued extension of the Museum, it should receive support from the State, as an institution intimately connected with the progress of biological science in this country."

With regard to the Scientific Collections of the South Kensington Museum, the Commissioners recommend :—

"The formation of a collection of physical and mechanical instruments ; and they submit for consideration whether it may not be expedient that this collection, the collection of the Patent Museum, and that of the scientific and educational department of the South Kensington Museum, should be united and placed under the authority of a Minister of State."

With regard to Provincial Museums, the Commissioners recommend :—

"That, in connection with the Science and Art Section of the Education Department, qualified naturalists be appointed to direct the collection of specimens in order to supply whatever deficiencies exist in the more important provincial museums ; and also in order to organise typical Museums, to be sent by the Department of Science and Art into the provinces to such Science Schools as may be reported to be likely to make them efficient instruments of scientific instruction.

"That a system of inspection of provincial museums be organised with a view of reporting on their condition, and on the extent to which they are usefully employed, and whether the conditions of the loan or grant from the Department of Science and Art have been fulfilled."

The final recommendations are on the subject of Lectures, and are : —

"That courses of lectures be given in connection with the collection of physical and mechanical instruments, the object of these lectures being to illustrate the progress of scientific and mechanical discovery and invention.

"That the establishment of lectures on Science, accessible to all classes on the payment of a small fee, should be promoted by the Government in the great centres of population.

"That, in the first instance with the view of carrying out the preceding recommendation, the system of instruction of this kind, which has already been established by the Government in the metropolis, should be developed by the institution of courses of lectures on the principal branches of Experimental and Natural Science.

"That the proposed lectures be of two kinds (1) lectures of an elementary character on the general principles and most important facts of Science ; (2) lectures specially intended for the working classes on the application of Science to the arts and industries of the country."

Until this Report was issued no general survey had ever been taken of our Museum system, if that can be called a system the growth of which has been almost entirely the result of accident. Both in the metropolis and in the provinces there exists a large number of museums and of collections of various kinds—to a large extent, however, connected with Natural History, and in local museums with Antiquities—but in almost every case, when the history of any of these institutions is traced, it will be found that it had its origin in quite an accidental way, and that no well-defined and intelligent system has been followed in the establishment of those institutions meant for public instruction. Some of the consequences of this capricious birth and untrained growth of the institutions referred to are that, especially in the metropolis, we have a heterogeneous collection of museums that have no relation

whatever to each other, each pursuing the even tenor of its way without any regard to its neighbours ; the collections in these museums often overlap each other, thus wasting means that might be expended to better purpose in developing some well-organised common system of aid to scientific research and instruction, and consequently some departments of Science are represented and endowed almost to excess, while others of at least equal importance are not represented at all ; and although all of them have ostensibly the same objects in view, viz. to afford facilities for scientific research and for the scientific instruction of the public, some are directly under the control of a Minister of State, others are not.

If the recommendation of the Commission, that the government of the British and Patent Museums be transferred to a department of State with a responsible Minister at its head, is adopted by the Government, no doubt some of these anomalies will be abolished ; the institutions will be made to fit into each other, and their government will be reorganised on some common and intelligent system, such as that recommended by the Commission.

One of the most glaring of these anomalies is the almost exclusive representation and endowment in our public museums of the Natural Sciences ; Botany, *e.g.*, being twice endowed, in the British Museum and at Kew—while the Physical Sciences, as if they were the illegitimate offspring of man and nature, are left to pick up a living as best they may, so that had it not been for their inherent vitality they would long ago have been starved out of existence.

In our Museums and Gardens, and elsewhere, aid to research in connection with the Biological Sciences is well provided for, while students of Botany, of Zoology, and of Geology in its various departments, have abundant facilities afforded them for the practical study of these sciences. The result is that there is nothing to check the career of these sciences ; they have been rapidly extending their domain, and may go on extending it still further without much anxiety as to where the sinews of war are to come from; all this with the very best results to our country. Our readers need no reminding of the immense strides recently made by Physical Science in its various departments, departments increasing in number and complication, and of the vistas of possible discovery of the most stupendous character which have been opened up, but for which private enterprise is utterly inadequate, and which must remain shrouded in mystery unless assistance similar to that which has been so amply accorded to the favourite Natural History Sciences be also given to the hitherto neglected Physical Sciences. Physical Science, though she sees many a glorious world that she longs to conquer, and whose conquest would be fruitful of the best results, can only in sadness let her hands dangle idly by her side, because unaided she cannot reach these fields of battle. No one competent to pronounce an opinion would venture to say that Physical Science has done less for the material prosperity of this country than Natural Science ; indeed within the last few years our rapid advance has been almost entirely owing to the practical application of physical discoveries. Yet what encouragement is held out to those who are able and willing to devote themselves to research which brings no profit to the researcher, but which is fraught with ultimate benefit to the race ?

The public, as we have shown, is made familiar in our museums with the results which have been reached in the Natural History Sciences, as well as with their *matériel*, but looks in vain for any exhibition of the instruments, the methods, and equally valuable results which belong to Physical Science ; hence, no doubt, partly the reason why the latter has been hitherto almost entirely left out in the cold; it is not known, and has but little opportunity of letting the public know its history and achievements, though it has something to show of at least equal value with the umbrella or the boomerang of a conquered savage. In chemistry, heat, light, sound, electricity, astronomy in its various branches—if a student wishes to have something more than a mere book knowledge of the methods of work and of the results obtained (and there are many such students), where can he obtain it in the same way as students of Zoology, Botany, Geology, Comparative Anatomy, and Physiology can carry on the practical study of these sciences? And yet no one, we dare say, would venture to give any better reason for this state of things than that Chance, which has hitherto governed the growth of our museums, has ordered it so.

There can be now, however, no possible excuse for the continuance of this anomalous system, seeing that the Report of the Commission has thoroughly exposed it, and suggested methods whereby to some extent its glaring defects and anomalies may be remedied. If Government wish to find a model for their guidance in reorganising and supplying the deficiencies of our public museums and institutions intended for the researches of students and for popular instruction, let them turn to Appendix III. of the Report of the Commission, containing the Report of the Secretary on the Aid given by the State to Science in France. In a previous article (vol. ix. p. 217) we referred to the disgraceful condition of our Patent Museum, and contrasted it with the magnificent Conservatoire des Arts et Métiers of Paris, extracts from the long and complete catalogue of which, as well as syllabus of its well-organised courses of lectures, will be found in the Appendix referred to.

"Evil is wrought by want of thought,
As well as by want of heart."

Government can no longer plead the excuse implied in Hood's lines for neglecting to remedy the evils so forcibly brought under their notice by the Report of the Commission. If means are not forthwith taken to organise our public museums and institutions for scientific research and instruction on some intelligent system, to supplement their lamentable deficiencies, and make them as widely beneficial to the advancement of Science in all its departments and conducive to the highest instruction of the public as they are calculated to be, it can no longer be set down to ignorance, but to an utter disregard to the highest welfare of the country. In this direction the new Government have a chance of distinguishing themselves and winning for themselves an enduring and worthy popularity; let them lose no time in showing their wisdom by appointing a responsible Minister of Education whose duty it will be to keep all our public scientific and educational institutions up to the highest pitch of efficiency, to re-organise them upon some common basis, and to see that the progress of research in all branches of Science is not hampered by the want

of adequate means for its pursuit. By such means will our rulers show themselves to be the real well-wishers and benefactors of their country.

TODHUNTER'S "MATHEMATICAL THEORIES OF ATTRACTION" *

A History of the Mathematical Theories of Attraction and the Figure of the Earth from the time of Newton to that of Laplace. By I. Todhunter, M.A., F.R.S. Two vols. (London: Macmillan, 1874.)

II.

OF the great Scotch mathematician, Maclaurin, we read—"The importance of his investigations may be seen by observing how great has been his influence on succeeding writers. Clairaut, D'Alembert, Lagrange, Legendre, Gauss, Ivory, and Chasles show by reference, explicit or implicit, their obligations to the creator of the theory of the attraction of ellipsoids.

Maclaurin well deserves the memorable association of his name with that of the great master in the inscription which records that he was appointed Professor of Mathematics at Edinburgh, "*ipso Newtono suadente*." His main contribution to the theory of the figure of the earth was an exact demonstration of Newton's postulate, of which only approximate solutions had previously been given. We may note on § 260 that we have seen the French version of his "Treatise on Fluxions," "traduit de l'Anglois, par le R. P. Pezenas, Paris, 1749; 2 vols." The first volume has li. pp. of Introduction; v.-viii. *Avertissement par le traducteur* ix.-li., Translation of Author's Preface and Introduction with *Table des Matières;* then 344 pp. of text, plates, and 4 pp. of errata. The second volume has viii. pp. of contents, 322 pp. of text, plates, with 6 pp. at end (4 pp. of errata), for errata, *approbation*, and *privilége*.

The next noteworthy name is again that of an English writer, Thomas Simpson. His contributions are of eminent importance. The analysis he employed, Mr. Todhunter observes, "would not have been unworthy of Laplace himself." There is here an interesting biographical note of a kind which the writer so well knows how to introduce, and which adds a charm to the more general details. In writing our notice we have especially dwelt upon the English contributors to our subject; on the whole it can hardly be denied "that Newton's countrymen have left to foreigners the glory of continuing and extending his empire." Singularly enough Mr. Todhunter gives no account of Simpson's work, "A New Treatise of Fluxions . . . with a variety of new and curious problems." London, 1737. 8vo. This is six years earlier than the "Mathematical Dissertations." Problems XXI. to XXIII. (§§ 201-206) deal with attractions of a circular plate on a point on the axis; of a cylinder on a point on its axis; of a sphere on a particle on its surface, or any distance above it, for law varying as inverse of (distance)^2 and for (distance)^n. They correspond to Problems II., IV., V., VI. of 1823 edition of the "Doctrine and Application of Fluxions."

The great work of Clairaut, "Théorie de la figure de la terre," &c., appeared in 1743. In this branch "no other person has accomplished so much as Clairaut; and the subject remains at present substantially as he left it, though the form is different. The splendid analysis which Laplace supplied adorned but did not really alter the theory which started from the creative hands of Clairaut." Laplace, too, places it "au rang des plus belles productions mathématiques."

The expedition to Peru gave rise to much paper warfare, and Mr. Todhunter has collected together, in a useful form, the titles of the original pamphlets. We think he has overlooked the following, "Nouveau projet d'une mesure invariable propre à devenir universelle, extrait d'un memoire lû . . . le 24 avril, 1748, par M. de la Condamine," viii. pp. A copy we have consulted of No. xx. (p. 236) is dated "Plombières, juin 30, 1754." (Consult Lalande, p. 455.)

D'Alembert need not long detain us. Laplace points out that his writings want "clarté." Mr. Todhunter says of him, "The errors of D'Alembert are certainly surprising; they seem to me to indicate that he was little in the habit of enlarging his own views by comparing them with those of others. His criticisms of Clairaut prove that he had not really mastered the greatest work which had been written on the subject he was constantly studying. His readiness to publish unsound demonstrations and absolute errors is abundantly shown in the course of our criticism. On the whole the blunders revealed in the history of the 'Mathematical Theory of Probability,' and in the present history, constitute an extraordinary shade on a fame so bright as that of D'Alembert."

Here we must give an account of a work not mentioned in the History. The "Considerazioni sopra la Figura della Terra"* of Tommaso Narducci appeared about the year 1747. It comprises two Lemmas (in modern geometrical conics they would be for the ellipse (1), GN equal $\frac{CB^2\, CN}{CA^2}$, (2) radius of curvature equal $\frac{PG^3\, CA^2}{CB^4}$), and nine problems. The first problem is "Dati due gradi di meridiano e loro latidudine, trovare la ragione degl' assi, e gl' assi stessi;" the last is "Data la ragione de' due assi, che sia di 1 ad m, trovare nel meridiano un grado, che sia eguale al grado dell' equatore." It is an interesting piece of geometrical work.

In his § 490 Mr. Todhunter considers it curious that the (Cambridge) University library does not possess a complete copy of the famous work of Stay and Boscovich. His surprise will probably be increased when we state that, if we are not mistaken, neither do the libraries of the British Museum or that of the late Mr. Graves; at any rate, we do not remember to have met with Boscovich's commentary on the poem. "These writings furnish elementary accounts of the most important results which had been obtained up to their date, and reveal apparently great knowledge and judgment in Natural Philosophy." A copy of Boscovich's "Dissertatio de telluris figurâ, habita in seminario romano Soc. Jesu nunc primum aucta et illustrata ab ipsomet auctore, P. R. J. Boscovich," forms pp. 161-218 of vol. ii. of Giuliani's memoirs (cited at the foot, date 1744). In p. 184 he speaks of Maclaurin's "Fluxions" as "Newtono ipso dignissima;" there is a noteworthy passage, pp. 217, 218, and also a notice on p. xii.

* Continued from p. 380.

* It occupies pp. 225-266 of vol. iii. of the "Memoria sopra la Fisica e Istoria Naturale di diversi valentuomini," edited by Carl Antonio Giuliani, in 4 vols. (1743-1747).

of the introduction of the volume.* The date on the copy of Frisi's dissertation (not seen by Mr. Todhunter) we consulted was 1751; it contains 8 pp. of *antecessio*; 86 pp. of text, 3 plates of figures, and 2 pp. of dedication. It consists of ten chapters, and may possibly, as Mr. Todhunter suggests, have been incorporated by Frisi in his "Cosmographia" (§ 532), though it certainly was not transferred bodily; on p. 65 he gets "axis terræ ad diametrum sibi normalem erit ut 229 : 230."

We have seen one of the works alluded to in § 551, viz., that of Bouguer; it is entitled, "Opérations faites par ordre de l'Académie . . . pour la vérification du dégré du méridien compris entre Paris et Amiens." Paris, 1757. 8vo. It consists of 28 pp., including two for title, and was read March 23, 1757.

In § 717 reference is made to the account of a measurement of an arc of the meridian in Lombardy by Beccaria, published at Turin "in 1744." We know of no work by Beccaria on this subject, except the "Gradus Taurinensis." The two copies of this which we have seen are dated 1774 and 1775; possibly from its position in the book the former of these dates is intended by Mr. Todhunter. It is a scarce work.

Mr. Todhunter has in § 725 devoted more attention to a supposed work by Newton than perhaps it really deserves. At any rate, De Morgan ("Budget of Paradoxes," p. 83) greatly doubts that Newton wrote it. He remarks that it has been treated with singular silence, and the name of the editor has never been given.

Lagrange contributes a memoir, in which he arrives by analysis at the point Maclaurin had reached by geometrical methods.

The operations carried on at Schehallien for ascertaining the density of the earth are next noticed, and with the conclusion of vol. i. the history of the two subjects during the century which followed the appearance of the "Principia" is nearly completed.

Some works mentioned as not having been seen (in § 738) may here be described.

The title of D'Anville's book is incorrectly given by Lalande.† For "*la* circonférence," read *sa*; for "*de l'équateur*," read *sur les parallèles*. There are 8 pp. of dedication (to Duc de Chartres), 20 pp. of *avertissement*, 3 pp. of *privilége*, &c, 11 pp. of observations, and 147 pp. of text, with a plate.

Lalande describes very accurately the contents of the "Anecdotes physiques et morales."

Mayer's "Basis Palatina" has 6 pp. of dedication, 14 pp. *lectori astronomo*; 23 pp. are taken up with "Series et ordo triangulorum quæ ex propriis suis observationibus, anno 1763 habitis, deduxit et correxit C. M.; 2 pp. of *conspectus totius operis*.

Hennert's work (Utrecht, 1778) contains five dissertations, of which the fourth is—"Sur le mouvement que prend un corps, quand il est parvenu au centre d'attraction, et sur l'attraction considerée comme principe universel." It takes up pp. 125-166. On p. 166 he says—

"Concluons de nos recherches qu'on n'a pas assès de preuves pour admettre l'attraction comme principe universel de tous les changemens qui arrivent dans le monde matériel. Nous avons vu que la cohésion des corps ne se déduit pas sans difficulté de l'attraction. . . . . Je sens bien, qu'il reste d'autres recherches à faire sur cette matière. J'en ai ebauché quelques unes que je pourrai publier si elles me paroissoient pouvoir contribuer au progrés des sciences physico-mathèmatiques."

His fifth dissertation is "Sur la figure de la terre relativement à la parallaxe de la lune et à la navigation." It occupies pp. 167-214. In § 18 we read, "Après avoir cherché inutilement de concilier les observations avec les hypothèses, dont les astronomes ont fait usage jusqu'aujourdhui, tachons de tirer un meilleur parti de notre formule générale," &c. And in § 25, "Il résulte de nos calcules que l'hypothèse de M. Bouguer et la notre donnent plus exactement le degré de longitude que l'hypothèse elliptique qui s'écarte considérablement de l'expérience." There are 4 pp. of dedication, 11 pp. of preface (interesting and amusing), 3 pp. of contents, 214 pp. of text, 2 pp. of errata, and 3 plates.

We may here describe a volume containing "Dissertationes de uniformitate motus diurni," by Hennert and Frisius, "præmio coronatæ," Petropoli, October 10, 1783. That by Hennert contains 42 pp., and *additamenta* making up 70 pp. in all; that by Frisius goes on to p. 112, and then 40 pp. more. They treat of attraction, but are not, apparently, of much importance.

Frisius it was who first introduced the ellipsoid as distinguished from the oblatum and the oblongum; from § 669, we learn, also, that he has no hesitation in adopting the truth as to the earth's motion.

Hube's work is in 87 pp. 8vo., with 1 page of plates. Its value may be seen from the following extract § 43:—

"Demonstravimus itaque tellurem nostram omnino esse homogeneam, vel potius densitatem variam illius partium, ratione universæ massæ, nullius fere momenti esse . . . probavimus porro, pendulorum experimentis, differentiam gravitatis sub polo et æquatore, tantam esse, ut terræ forma elliptica omnino esse nequeat . . . ad finem itaque meum pervenisse mihi videor, qui tantum fuit, ut experimentorum hucusque factorum ope, summâ qua fieri potuit evidentiâ, telluris formam certo definirem ac omnia dubia, quæ in hac re jure moveri possent, tollerem; neque adeo immorabor in consectariis variis nostræ theoriæ explicandis, quoniam vera telluris forma semel certo stabilita, haud difficile est, eo colligere atque perspicere, quæ inde necessario efficiuntur."

Further particulars concerning Thomas Williams (§ 988) are given in the "Budget of Paradoxes," p. 102.

The work referred to in § 1,000, is a 4to. volume, and contains 1 page of *avertissement*, 13 pp. of introduction, 1 page of table, 94 pp. of text, and 1 page of errata (in this Houslowheat is corrected to Hounslowheat). We think we have somewhere seen the preface ascribed to Legendre; it is clear, however, from the introduction (from the words "deux de mes confrères de l'Académie M.M. Mechain et Legendre, p. xiv.) that it is due to Cassini, as Lalande correctly states. With the copy we examined was bound up "Descriptions des moyens employés pour mesurer la base de Hounslow Heath dans la province de Middlesex, publiée dans le vol. lxxv. des 'Trans. Phil.' par le Major-Général William Roy, traduite de l'Anglais par M. de Prony," Paris, 1787. There is a *discours préliminaire du traducteur* 18 pp. There is a notice of 1 page, a page of errata: the translation occupies 80 pp., there are 3 tables, and 5 planches. Mr

* We have also seen another work, the "De centro Gravitatis, editio altera, accedit disquisitio in centrum magnitudinis" (Rome, 1751), but it does not, if we remember, bear upon our subject.

† There is a very valuable copy of this work ("Bibliographie Astronomique") in the Graves' Library, containing Lalande's autograph notes, and many other interesting features.

Todhunter gives no account of this work: it is apparently a translation of the work described in § 984.

The following work by Delambre and Legendre (will this throw light on § 1,146?) does not seem to be described: it is "Methodes analytiques pour la détermination d'un arc du méridien précédées d'un memoire sur le même sujet," par A. M. Legendre. Paris, 1799. 4to.) In note ii. to "Methode pour determiner la longueur exacte du quart du meridien," par A. M. L. occurs *Legendre's Theorem.* There are 176 pp., 16 pp. of tables at the end, 5 pp. of "Observations sur quelques endroits du mémoire du cit. Delambre," par A. M. Legendre; 2 plates, 7 pp. of *avertissement*, and 4 pp. of contents.

We now close our notes with a few remarks on §§ 531, 682, and 1,584. The memoir, which neither Playfair nor Mr. Todhunter have been able to procure a sight of, is to be met with in vol. i. of the Giuliani memoirs cited above, consequently its date is antecedent to 1743. It occupies pp. 65-88, and is entitled "Problema mecanicum de solido maximæ attractionis solutum, a P. Rogerio Josepho Boscovich." The problem is, "Data quantitate materiæ punctum attrahentis, in quacunque lege distantiarum invenire solidum ipsum continens, quod maximè omnium attrahat ipsum punctum positum in axe solidi producto ad datam distantiam ob ipsius solido vertice propiore." The author gives a geometrical and an analytical solution of the problem, and concludes, "Solutio geometrica in eo huic posteriori præstat quod ibi determinatur solidum maximæ attractionis etiam inter solida omnia irregularia, hic tantum inter solida genita rotatione curvæ circa axem."

The greater part of this second volume is taken up with the important writings of Laplace, Poisson, Gauss, Ivory, and Plana.

In the case of Laplace, who was, like some other writers, not in the habit of acknowledging his indebtedness to preceding authors, the result of the investigations is to restore his reputation to its proper eminence. "In the present history, and in that of Probability, I have gone over a third part of the collected mathematical works of Laplace; and to that extent the evidence of his great powers and achievements is, I hope, fully and fairly manifested."

Our work is now nearly done; were we to make use of all our notes, we might easily double and treble what we have written.* We have noted upwards of fifty articles which are interesting as sidelights: thus, § 227, Bouguer's remarks on what we now call the "personal equation;" § 710, transformation of variables in a triple integral, and many others. The value of the index would have been enhanced had reference been made to these; as it is, the index is much fuller than in the earlier volumes, and we have detected but few errors. This is no new feature, for all Mr. Todhunter's books are most carefully got up in this respect, and we have not met with a single important error in the mathematical work; the few mistakes we have come across are easily corrected.

There are indications here and there throughout the volumes that, should the writer be able to secure the requisite leisure, he will not want for subjects to exercise his special gifts upon. We sincerely hope that he will do so at an early date, and that it may be our lot to read the results. In the course of the preparation of the present work Mr. Todhunter has published, in the Royal and other Societies' proceedings, various papers which have grown out of his investigations in the history of our two subjects.*

R. TUCKER

* In our remarks we have preferred to treat the subjects from an historical rather than from a mathematical point of view.

* Possibly some further memoirs of use might be found in the "Librorum in Bibliothecâ Speculæ Pulcovensis, anno 1858, exeunte contentorum catalogus systematicus," by Otto Struve. Petropoli, 1860.

TRAINING

Training in Theory and Practice. By Archibald Maclaren. Second Edition. (Macmillan & Co., 1874.)

WHEREVER we go, "The Boat Race" is the topic of the hour. Opinions are freely expressed as to the relative merits of the rival crews; and the risks and dangers incurred during the process of training, sturdily insisted on by some, are as obstinately denied by others. The respective values of the slow and quick stroke—the American fashion of "sliding-seats," and a variety of kindred questions, are eagerly debated, occasionally by men who really understand what they are talking about, but more frequently in order to make conversation, or, as the phrase goes, "for the sake of something to say."

In such a state of the public mind, it has by a happy chance been so ordered that the second edition of Mr. Maclaren's well-known work on Training should appear, at a moment when all will take unusual interest in its contents.

From a perusal of this treatise everyone may gather information calculated to be of service to him, not only for the time being but for the future. The man who likes to know a little of everthing, may with advantage indulge his curiosity about a subject which has perhaps hitherto been out of his line; while the father with a son in "the eight," and whose mind has been disturbed by letters in the papers, hinting at dire mischief as the outcome of training, may find substantial comfort in its pages. All those who, either from necessity or for amusement, undergo much physical exertion, will do well to imbue themselves with the author's teaching; and the "man of ease" or of sedentary occupation will find hints for health or sanitary lessons of a description which, if honestly carried out, would cause the ruin of half the doctors in London.

Mr. Maclaren uses "rowing" as the peg on which to hang his theme, and the reason he gives for so doing is as follows:—

"It is the exercise most susceptible of being influenced by a judicious system of bodily preparation, being at once an act of considerable intricacy, demanding long and assiduous practice, and an exercise of considerable difficulty, involving the possession, although not in an equal degree, of both muscular and respiratory power, to promote which is the object of all training."

The question, what is training? and what is it meant to do? he answers thus:—"It is, to put the body with extreme and exceptional care under the influence of all the agents which promote its health and strength, in order to enable it to meet the extreme and exceptional demands upon its energies." There can be no doubt that the essence of this paragraph is contained in the words "extreme and exceptional care;"—for without such care,

instances are furnished to alarmists of men "fainting by the way," and a highly valuable art is in danger of being brought into disrepute. We have no fear for the men engaged in a great race like that which takes place on Saturday—they have been carefully instructed in the proper method of training—all that experience has taught has been lavished on them, and the result is, as Dr. Morgan's statistics show, that they live as long as other portions of the civil community.

But on the other hand we do fear for the many persons who assert that they are in training for some race or other physical feat, but from whom on inquiry we learn that their notions and practice are so desultory, and so deficient in anything like scientific detail, that it is an abuse of the word training to apply it to their misdirected proceedings. They forget, or at least do not sufficiently consider, that the feat they are about to attempt will require of them, at some critical moment, a supreme effort; and that in the making of this effort, a lasting injury may be inflicted upon a frame that is only imperfectly prepared.

To them we say, "if a thing is worth doing at all it is worth doing well." Train thoroughly or not at all—you have no right to jeopardise your future by "extreme carelessness" when all bad results may be avoided by "extreme care."

In former times Diet was looked upon as of paramount importance among the agents of health in training; Mr. Maclaren, however, places exercises in the front rank, and justifies himself for doing so in the following logical and telling words:—"So long as men believe that the qualities which they covet are to be obtained from mere dietary regulations, they will neglect the real agencies which can alone bestow them; exercise, the one agent which gives, which can give, these qualities, both from its own nature and from the influence which it exerts upon all other agents of health, is, in a measure, neglected, nay, avoided, and to the imaginary virtues of diet men look for the longed-for acquisitions; they have yet to learn, they have yet to know, and to themselves realise, that power of muscle in trunk and limb, that freedom and capacity of heart and lung, that energy, stamina, strength and endurance, are not to be obtained from what they *eat*, but from what they *do*."

To each of these subjects, Exercise and Diet, a separate chapter is devoted; and each is treated in a masterly and exhaustive manner. Our space will not, however, permit of more than an allusion to them. Mr. Maclaren deprecates the error of confining the attention to any one form of exercise, on the ground that it must be insufficient to produce the desired result, that is to say, the increased action, and thereby the fuller development, of all the muscles of the body. He illustrates his meaning by the example of the man who, having one favourite author or favourite object of study, fails to cultivate or employ his *whole* mind. On the subject of Diet he is much less stringent and exclusive than is customary, and we think rightly so, recognising the fact that each one must be a law to himself; whence the truth of the trite saying, "What is one man's meat is another man's poison." His views on this point may be summed up in his own words: "I would only advocate the rational system of not suddenly breaking in upon a man's fixed habits, at the time you are asking for an effective display of his greatest bodily energies."

Another moot point, the question of the amount of sleep required by different persons under the same circumstances, is next discussed. No hard and fast rule is laid down, but the breadth of view that is one of the great charms of the book is again apparent. The opinion is expressed that the time to be devoted to the purpose should vary not only with the individual, but with the same individual at successive periods of life, and that the wants of the system, in this respect, are influenced by various causes, and by the action of the other agents of health, especially by exercise. With reference to this matter, we have frequently observed that tall persons require a longer period of recumbency than short, whose hearts are called upon for less powerful exertion, by reason of the smaller height of the column of blood that they have to sustain and propel.

The chapters next in order deal with the important but still subsidiary questions of air, bathing, and clothing. We cannot at present enter into detail with regard to any of these subjects, but we would add to Mr. Maclaren's observations on bathing, that one great secret of using a cold bath in the dressing-room without discomfort or injury, is to sit down in the water in the first instance, and to wash the upper part of the body, thus somewhat raising the temperature of the water before the feet are immersed.

The concluding portion of the book is devoted to very clear and practical directions for self-training for aquatic purposes, and in this, as in all other parts, it will be found a complete and trustworthy guide by those for whose use it is intended.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Herbert Spencer versus Thomson and Tait

A FRIEND has lent me a copy of a pamphlet recently published by Mr. Herbert Spencer, in which certain statements of mine are most unsparingly dealt with, especially in the way of attempted contrast with others made by Sir W. Thomson and myself. I am too busy at the present season to do more than request you to reprint one of the passages objected to (leaving it to your readers to divine to what possible objections it is open), and to illustrate by a brief record of my college days something closely akin to the mental attitude of the objector.

"Natural philosophy is an experimental, and not an intuitive science. No *à priori* reasoning can conduct us demonstratively to a single physical truth" (Tait, *Thermodynamics*, § 1).

One of my most intimate friends in Cambridge, who had been an ardent disciple of the late Sir W. Hamilton, Bart., and had adopted the preposterous notions about mathematics inculcated by that master, was consequently in great danger of being plucked. His college tutor took much interest in him, and for a long time gave him private instruction in elementary algebra in addition to the college lectures. After hard labour on the part of each, some success seemed to have been obtained, as my friend had at last for once been enabled to follow the steps of the solution of a question involving a simple equation. A flush of joy mantled his cheek, he felt his degree assured, and he warmly thanked his devoted instructor. Alas, this happy phase had but a brief duration; my friend's early mental bias too soon recovered its sway, and he cried in an agony of doubt and despair, "But what if x should turn out, after all, *not* to be the unknown quantity?"

Compare this with the following extract from Mr. Spencer's pamphlet:—

"... if I examine the nature of this proposition that 'the properties of matter *might have been*' other than they are. Does it express an experimentally-ascertained truth? If so, I invite Prof. Tait to describe the experiments!" P. G. TAIT

Animal Locomotion

MY former letter on this subject was merely to show that, mechanically, Dr. Pettigrew's view of the forward motion or inclination of a bird's wing during the down stroke was less absurd than had been supposed, and even seemed necessary to flight. I did not profess to have made accurate observation or experiment on the point. I accept, therefore, the observation of the Duke of Argyll as to the vertical motion of the heron's wing; but as he expressly refers to its great concavity, that would give a vertical down stroke the effect of a somewhat forward stroke of a flatter wing. The proper inference would therefore seem to be, that in birds with less concave wings the stroke is slightly directed forwards. As to the last two paragraphs of his Grace's letter, he will see, if he refers again to mine, that he has quoted words I never used. I impute to Dr. Pettigrew the "merit of showing" that the "*slight upward angle* of the mean position of the wing plane is essential to secure horizontal forward motion *as* a general resultant," &c., and this is exactly what the Duke denies.

Mr. James Ward's elaborate analysis of the down stroke of a bird's wing simply shows (if correct) that in the position he ascribes to it (moving downward and backward) it would send the bird horizontally forward. Of course it would. But then what becomes of the bird during the up stroke in an opposite direction? The bird is then falling, and by the downward reaction of all the solid surface of the anterior margin of the wing, and of all the feathers, however obliquely turned, it is driven farther downwards; and as this takes place between every two down strokes, and approximately during an equal space of time, how is a horizontal average motion to be produced unless the down stroke alone produces, not a horizontal, but a highly-inclined upward motion? Mr. Ward's whole argument appears to me to ignore the great downward reaction, added to gravitation, during every up stroke, which requires that the down stroke should not merely support the bird, but raise it up vertically just as much as during the up stroke it has fallen vertically. The matter, however, is not to be settled by discussing theoretically, but by observation and experiment. I simply maintain that the results of Dr. Pettigrew's observations and experiments are not, as supposed, inconsistent with mechanical principles; and nothing in your correspondent's letter induces me to alter that opinion.

ALFRED R. WALLACE

The Newfoundland Cuttle-Fish (*Megaloteuthis harveyi* S. Kent)

MY right being questioned, through an anonymous paragraph in the *Globe* of the 11th inst., to institute a new generic title for the gigantic Cephalopod encountered off Newfoundland, and of which I communicated an account to the Zoological Society's meeting of March 3, I would briefly reply to my criticiser in these columns.

In the first place, it is a somewhat anomalous proceeding to raise objections on such a question before details of the grounds upon which it has been deemed advisable to establish such a title have appeared, as in the ordinary course of events they will, in the "Proceedings" of the Society. In these it will be found that ample reasons are given for the course that has been taken, as also due notice of both Prof. Steenstrup's and Prof. Verrill's researches in a similar direction. Had my assailant placed himself more thoroughly *au courant* with the details of the case, he would possibly have held back his emphatic assertion that Prof. Verrill had "actually identified the species from Newfoundland with those described by Steenstrup as belonging to his genus *Architeuthis*." This identification in Prof. Verrill's own language is entirely problematical, and must unfortunately remain so, since a beak only, an organ of no value in generic discrimination, has been preserved of the typical species *A. dux*. Respecting the second form, *A. monachus*, we have still less knowledge, the title being provisionally instituted by Prof. Steenstrup for the reception of two gigantic Cephalopods cast on the shores of Jutland in the years 1639 and 1790, and of which popular record alone remains.

In reference to the "imperfect evidence" asserted by my critic to be at my command, I may state that I received accounts of the examples, upon which I have proposed to base my new title of *Megaloteuthis*, direct from America as long ago as in the beginning of December last, supplemented by numerous fuller details since.

W. SAVILLE-KENT

Lord Lindsay's Expedition

THE expedition of Lord Lindsay for observation of the Transit of Venus at Mauritius (why will people still call it *the* Mauritius?) will afford a good opportunity for re-measuring the base line of Abbé de la Caille, made in 1753, and which, to the best of my belief, has never been since verified.

The small conical cairns which mark its extremities should still be found *in situ*. I saw one only of them in November 1864, when I had not time to search for the other. The base measured was 1,828 toises in length, and, I imagine, on the meridian. It was on a level plain at the south-west extremity of the island, close under the western slopes of the precipitous and noble "Morne du Brahant," which rises nearly 1,700 feet above the sea-level. By road the distance of this spot from Port Louis must be at least 30 miles, but it is much more easily reached direct by boat; or, as December is a bad time of year for boating outside the reefs, the best route would be from Black River by water inside the isle Bénitier. It is a glorious district, all that part of the island, and contains the finest scenery, including the Chamaral Falls.

S. P. OLIVER

Buncrana, near Londonderry, March 14

QUETELET

ON February 17 last Jacques-Adolphe-Lambert Quetelet died at Brussels, in the seventy-eighth year of his age, having been born on February 22, 1796, at Ghent. At the early age of 18 he was appointed Professor of Mathematics in the College of his native town. In July, 1819, the degree of Doctor of Science was conferred on him by the University of Ghent, then recently founded by King William. His dissertation on this occasion was so well received that he was shortly thereafter appointed to the Chair of Mathematics at the Royal Athenæum of Brussels; and in February following was elected a member of the Academy of Sciences and Belles-Lettres.

At this time he applied himself with ardour to the cultivation of literature and pure mathematics, thus laying a sure foundation for the world-wide fame he afterwards achieved as an exact investigator in many departments of physics, as an original thinker in applying methods of scientific treatment to the discussion of problems previously considered as belonging exclusively to moralists and divines, and as a clear and eloquent expounder of the truths he had demonstrated. The many-sidedness and fertility of his mind may be seen from his scientific memoirs enumerated in the Royal Society's Catalogue of Scientific papers, amounting at the close of 1863 to 220. He continued to write almost to the last, notwithstanding the mental malady, consisting in loss of memory, with which he was afflicted many years before his death, and it is noteworthy that even to the last his handwriting retained much of the rare grace and elegance for which it had been so remarkable.

The earliest of Quetelet's published memoirs, begun in 1820, were on geometrical subjects. The non-appreciation of these by the public determined him to devote himself to physical science and astronomy. On these subjects he lectured publicly with great success.

In 1823 he was sent on a mission to Paris with the view of preparing a report on the observatory of that city for the guidance of the Belgian Government in founding a similar observatory at Brussels. After some delay, the observatory was established, with Quetelet as director, and in 1833 began the long series of observations on astronomy, meteorology, and other physical inquiries, for which this observatory is so well known. The most important of his astronomical observations was the prepara-

tion of a catalogue, begun in 1857, of stars which seem to have appreciable motion. He also began, so early as 1836, systematically to observe and record the occurrence of meteors and shooting-stars. These observations came to be of great value thirty years later, when the true nature of these bodies was satisfactorily established.

The meteorological observations at this observatory have been particularly full and valuable, embracing hourly and bi-hourly observations, published annually *in extenso*, of atmospheric pressure, temperature, humidity, rain, cloud, &c. These have been exhaustively discussed by Quetelet in "La météorologie de la Belgique comparée à celle du globe," published in 1867. In this admirable treatise we have what must still be regarded as the fullest and best account of the meteorology of any single locality on the globe—the yearly, monthly, daily, and hourly march of the various meteorological elements being given. In the same volume are given *résumés* of the observations made at the other stations which began to be established at Alost, Ghent, Liége, &c., in 1835.

He was elected perpetual secretary of the Academy of Sciences and Belles-Lettres in November 1834, and was chiefly instrumental in adding a section on the Fine Arts in 1845. It is scarcely necessary to refer to the scientific contributions he made to the Fine Arts, by his extensive and minute investigations regarding the proportions of the human body, the results of which are given in his "Anthropométrie." In matters relating to the higher education, to the census, and other national questions, the Belgian Government wisely availed itself repeatedly of his wide knowledge and great experience.

His first paper on the subject of statistics was published in 1826; in 1835 appeared his "Physique sociale," and ten years later his "Lettres sur la théorie des probabilités appliquées aux sciences morales et politiques." In 1841 a Central Commission of Statistics was established by royal decree, of which Quetelet was made president, and of which he continued to be president to his death. He originated the idea of convening an International Congress of Statistics. The first was held in Brussels in 1853, and others have since been held at Paris, London, Berlin, Florence, the Hague, and St Petersburg. It is in the field of statistics that Quetelet appears as a great discoverer, and his success in this department must be attributed to the clearness with which he saw that statistics occupy the ground in the development of the social and political sciences which observational data do in the development of such sciences as astronomy and meteorology, to the patient industry with which through long years he gathered together his facts, and to the mathematical skill he brought to bear on the discussion of the results. He was truly, as expressed by the Academy of Berlin in their congratulatory letter on the occasion of the centenary of the Belgian Academy, "the founder of a new science which proceeds from the firm basis of observation and calculation to discover and unfold those immutable laws which govern the phenomena, apparently the most accidental, of the life of man, down even to his most trivial actions."

SCIENTIFIC RESULTS OF THE "POLARIS" ARCTIC EXPEDITION

WE have received advanced sheets of the Report of the Secretary of the United States Navy, of the examination of those of the crew of the *Polaris* who were in the ship when she broke loose from the floe to which she was anchored, on October 15, 1872, leaving the nineteen persons on the sheet of ice which was their floating home, until picked up about six months after off the coast of Labrador (NATURE, vol. viii., p. 217). This report confirms the opinion we have already expressed that no Arctic expedition can be adequately conducted unless carried out under naval discipline. It was only on account of the good intentions and good nature of the crew, especially after their noble and enthusiastic captain's death, that things went on as smoothly as they did. Captain Buddington seems to have had no heart in the object of the expedition, and we cannot help thinking that had he not been with it much more would have been gained. It was in deference to his opinion that Captain Hall refrained from trying to push beyond his furthest point (82° 16′ N.) with the ship; all the other officers, though they do not seem to have been very well assorted, being of opinion that an attempt should be made to get further north, or at least not to lose ground by wintering further south.

We have already (vol. viii., p. 435) given details as to the rescue of those who were left in the *Polaris*, and of their being landed in Scotland by the *Arctic* and *Eric* whalers. The present report affords some idea of the scientific results of the expedition, a detailed account of which will no doubt by and by be published, although we regret to see that many of the records of the scientific results were lost in the confusion incident to the parting of the ship from the floe. Still much that is valuable has been brought home, from which many additions to a scientific knowledge of that part of the Arctic region will be obtained. Notwithstanding the want of perfect harmony among the officers, the scientific work of the expedition seems to have been diligently carried on, and the evidence of Dr. Bessels especially contains a great deal of value to Science. Geographers will be able to correct and extend their maps of the regions visited, and we hope that very soon the complete material for enabling them to do so will be in their hands. Constant and careful tidal observations were carried on, with the very valuable result of ascertaining that the tide of Thank-God Harbour, 81° 38′ N. is not produced by the Atlantic but by the Pacific tidal wave. "It was found," Dr. Bessels says, "that the co-tidal hour is about $16^h\ 20^m$. Rensselaer Harbour, being the northermost station, has its co-tidal hour at $18^h\ 04^m$, consequently the tide comes from the north, the rise and fall at spring-tides amounting to about 5 ft.; at neap tides $2\frac{3}{10}$. Most likely the two tidal waves meet somewhere in Smith Sound, near Cape Frazier. Kane and Hayes have both found a ridge of hummocks near Cape Frazier, and in drifting down we experienced that during some time, being abreast of Cape Frazier; we hardly made any headway, but we drifted both north and south."

The results of the expedition may be summed up briefly as follows:—(1) the *Polaris* reached 82° 16′ N., a higher latitude than has been attained by any other ship; (2) the navigability of Kennedy Channel has been proved beyond a doubt; (3) upwards of 700 miles of coast-line have been discovered and surveyed; (4) the insularity of Greenland has been proven; and (5) numerous observations have been made relating to astronomy, magnetism, force of gravity, ocean physics, meteorology, zoology, ethnology, botany, and geology, the records of which were kept in accordance with the instructions supplied by the National Academy, and some of the results of which we propose briefly to enumerate.

ASTRONOMY.—Great care was taken in determining a reliable meridian at Thank-God Harbour. Soon after entering winter-quarters an observatory was erected on the shore, thirty-four feet above mean sea-level, and the transit instrument stationed there. The longitude of this station was determined by the observation of 300 lunar distances; a number of moon culminations; a great number of star transits; a number of star occultations; a great number of altitudes of the sun on or near the prime vertical. Its latitude, by the observation of a great number of circummeridian altitudes of the sun, and a number of altitudes of stars. All of these observations were lost, but a number of the results have been preserved which are sufficient to establish the position of his station.

The instruments used in the above observations were a Würdemann transit and Gambey sextants divided to 10". The expedition carried six box chronometers made by Negus, three of which indicated sidereal time, and four pocket chronometers by different English makers. These time-pieces were compared every day at precisely the same time, and the result entered in the chronometer-journal.

Besides the above-mentioned observations, twenty sets of pendulum experiments were made, which are saved, but the observations for time belonging to them are lost.

MAGNETISM.—The magnetic observations obtained were more complete than any others ever before made in the Arctic regions. The instruments supplied were:—one unifilar declinometer; one dip circle, with Lloyd's needles; one theodolite; and several prismatic compasses.

The observations on variation of declination were registered at Göttingen time, and were continued for five months: readings taken hourly. Besides that, three term days were observed every month, according to the Göttingen regulations, one of these term days corresponding with the day accepted by all the magnetic stations. Further, a number of observations were taken either with the theodolite or the prismatic compass. Whenever possible, the dip was observed, and several sets of observations on relative and absolute intensity and of the moment of inertia were obtained.

OCEAN PHYSICS.—Unfortunately there was not much opportunity for taking soundings. About twelve were obtained along the coast of Grinnell Land, which prove that the hundred-fathom line follows the coast at a distance of about 15 miles in Smith's Sound. One of these soundings (90 fathoms) proved highly interesting, containing an organism of lower type than the *Bathybius* discovered by the English dredging expedition. It was named *Protobathybius robesonii*.

A number of deep-sea temperatures were taken with corresponding observations on the density of the water. Following the coast of West Greenland the limits of the Gulf Stream were ascertained. Specimens of water from different depths were preserved in bottles, but were, unfortunately, lost.

As soon as the vessel was fairly frozen in, a tide-gauge was erected over a square hole cut in the ice-floe, and kept open continually; the pulley and rope were supported by a tripod of oars. A rope, to which a wooden scale, divided into feet and inches, was fastened, was carried through a block attached to the tripod. One end of the rope was anchored at the bottom by means of two thirty-two pound shot, and a counterpoise was attached to the other end to keep the rope properly stretched. This apparatus was tested by a series of scale readings with corresponding soundings, and proved to work very satisfactorily. The observations comprise eight lunations, the readings being taken hourly, half-hourly, and in some instances every ten minutes, in order to determine the precise moment of the turn of the tide.

METEOROLOGY.—After having entered winter-quarters meteorological observations, which up to this time had been made three-hourly, were made every hour, Washington time. The register contained observations on the temperature of the air, atmospheric pressure, psychrometrical observation, direction and force of wind, appearance of the sky, state of weather, and both solar and terrestrial radiation. Besides, all extraordinary meteorological phenomena were carefully noted.

For the registration of the temperature of the air mercurial thermometers were used for temperatures down to $-35°$ F.; for lower ranges spirit instruments being compared at intervals of 10°. As circumstances would permit, mercurial or aneroid barometers were used. As it was not supposed that psychrometrical observations could be favourably conducted at very low temperatures, the expedition was not supplied with the suitable instruments. For that reason two uncoloured spirit thermometers were selected and used, the readings of which agreed. As check observations the dew-point was determined by means of Regnault's apparatus. To measure the velocity of the wind, Robinson's anemometer usually served. The distance travelled by the wind was noted hourly, at the same intervals of time. The velocity of the wind was determined either by the same instrument or by means of Casella's current-meter. These observations on the winds, combined with those on moisture of the atmosphere, will form a valuable contribution to physical geography.

It was not thought essential to procure photographs of the clouds, as they do not differ in their general character from those in more southerly latitudes. The only remarkable fact to be noticed is that sometimes cirri could be observed at very low altitudes among stratus clouds, which, however, is not surprising if their mode of formation is taken into account.

Special attention was devoted to the aurora borealis, which occurred frequently, but rarely showed brilliant colours, never bright enough to produce a spectrum. Whenever necessary one observer was stationed at the magnetometer and the other out-doors, the former observing the motions of the magnets, while the other was watching the changes in the phenomenon and taking sketches. Although an electroscope and electrometer were set up, and the electrical condition of the atmosphere frequently tested, in no instance could the least amount of electricity be detected. The amount of precipitation was measured as carefully as the violent gales would permit, by means of a rain-gauge supplied with a funnel. In February, as soon as the sun re-appeared, observations on solar radiation were commenced, and continued throughout the entire summer. The instruments employed were a common black-bulb thermometer, and one *in vacuo*; both exposed on white cotton.

ZOOLOGY AND BOTANY.—The collections of natural history are almost entirely lost. With the exception of two small cases containing animals, minerals, and one package of plants, nothing could be rescued. The character of the fauna is North American, as indicated by the occurrence of the lemming and the musk ox. Nine species of mammals were found, four of which are seals. The birds are represented by twenty-one species. The number of species of insects is about fifteen, viz.: one beetle, four butterflies, six diptera, one bumble-bee, and several ichneumons, parasites in caterpillars. Further, two species of spiders and several mites were found. The animals of lower grade are not ready yet for examination.

The flora is richer than could be expected, as not less than seventeen phanerogamic plants were collected, besides three mosses, three lichens, and five fresh-water algæ.

GEOLOGY.—Although the formation of the Upper Silurian limestone, which seems to constitute the whole west coast north of Humboldt Glacier, is very uniform, some highly interesting and important observations have been made. It was found that the land is rising, as indicated, for instance, by the occurrence of marine animals in a fresh-water lake more than 30 feet above the sea-level and far out of reach of the spring-tides. Wherever the locality was favourable the land is covered by drift, sometimes containing very characteristic lithological specimens, the identification of which with rocks in South Greenland was a very easily accomplished task. For instance, garnets of unusually large size were found in latitude 81° 30′, having marked mineralogical characteristics by which the identity with some garnets from Fiskernaes was established. Drawing a conclusion from such observations it became evident that the main line of the drift, indicating the direction of its motion, runs from south to north.

THE COMMON FROG*

XII.

So much for the circulation of the frog in its adult condition. Its larval, or tadpole stage, presents us with a series of changes which, though more familiar, are not less wonderful.

In the first place, however, it may be well to describe shortly the condition of the circulation in fishes, where the purification of the blood is effected, not by means of the exposure of the blood to the action of air taken into respiratory cavities of the body, but by its subjection in little plates of membrane, the gills, to the influence of air mechanically mixed up with and dissolved in the water in which those gills are bathed.

In fishes, moreover, unlike all air-breathing animals, none of the oxygenated blood is returned to the heart for propulsion, but is collected directly into the great dorsal aorta, whence it is distributed to the whole body, only being returned to the heart after such distribution, so that venous blood alone enters that organ.

This venous blood is sent out from the heart through a bulbous aorta, whence arise on each side a series of arteries which ascend the branchial arches, one on the outer side of each such arch, decreasing in size as it ascends.

Each branchial artery gives off small gill arteries, which run along one edge of each little membranous leaflet or gill, and supply it with minute branches ending in capillaries, in which the blood is purified. There the purified blood is taken up by minute veins which open into gill veins, one of which runs along the opposite edge of each gill to that occupied by the gill artery.

The gill veins pour their contents into branchial veins, one of which ascends the outer side of each branchial arch, increasing in size as it ascends. The branchial veins open into the great dorsal aorta, whence the blood is distributed over the body. Generally the branchial arteries are only connected with the branchial veins by the intervention of the capillary vessels of the gills. Sometimes, however (as *e.g.* in the mud-fish, *Lepidosiren*), the branchial veins are directly continuous with the branchial arteries.

In the tadpole, while the gills remain fully developed, a condition exists quite similar to that of fishes. Minute vessels, however, directly connect together, at the root of each gill, the branchial artery and branchial vein of each gill. Such a connecting vessel is termed a *ductus botalli.*

A minute vessel given off from the third branchial artery, is the incipient pulmonary artery.

As development proceeds, as the gills diminish by absorption, and as their respective arteries and veins decrease in size and importance, each *ductus botalli* increases until at last we have established the six great continuous vessels of the adult frog.

We have, then, in the life-history of the frog, a complete transition from the condition of the fish to that of a true air-breathing vertebrate, as regards its circulation. The various conditions herein referred to have, however, an important bearing on the question of the first origin of such structure.

All higher animals, even the very highest, have the great arteries, when they first appear, arranged substantially as in fishes.

From the common aortic bulb five vessels ascend each side of the neck, and more or fewer of these arteries abound in different classes, the permanent adult condition being arrived at by this circuitous route.

This argument has commonly been adduced as an argument in favour of the descent of air-breathing animals from more ancient gill-bearing forms, and it is not without weight.

* Continued from p. 369

Nevertheless it must be borne in mind that the primitive condition in Fishes is that of direct continuity between the branchial arteries and veins such as we have seen exists permanently in *Lepidosiren*. It is only as development proceeds that each primitive continuous arch

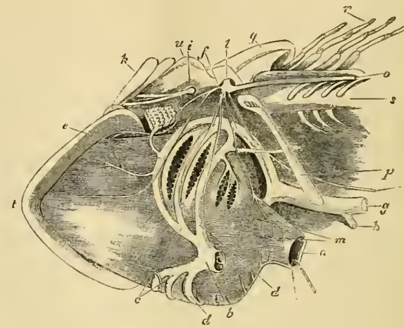

FIG. 78.—Infero-lateral view of Head and Aortic Arches of Lepidosiren (after Hyrtl). *a*, œsophagus; *b*, anterior end of bulbus aortæ; *c*, common roots of the first aortic arches; *d*, third aortic arch; *e*, first aortic arch; *f*, dorsal union of the first three aortic arches; *g*, aorta; *h*, cœliac artery; *i*, exit of the fifth nerve; *k*, part of operculum; *l*, exit of the nervus vagus from the skull; *m*, branches to œsophagus; *n*, nerve going to the rectus abdominis; *o*, nervus lateralis; *p*, first and hypertrophied rib; *q*, posterior part of the skull; *r*, segmented neural spines; *s*, chorda dorsalis; *t*, mandible; *u*, quadrate.

becomes broken up into an artery and a vein connected by a net-work of capillaries.

Now we can understand the series of unbroken arches in higher animals as the relics of ancestral vessels which divided for gill circulation and were therefore once of extreme functional importance and utility. But how can we understand the primitive unbroken series of arches in Fishes? Their utility was yet to come!

The frog when adult has, besides its skin, no breathing organs but the lungs. As has been said before, other members of the Frog's class retain gills and aquatic respiration during the whole of life, as for example *Menobranchus.*

Every one kind, however, whether provided permanently with gills or not, develops lungs, and it might easily be imagined that similarly every gilled-creature which has lungs is also a Batrachian.

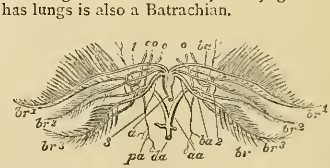

FIG. 79.—The Circulation of a Tadpole in its primitive stage, when nearly all the blood is distributed to the gills; the pulmonary arteries being quite rudimentary, and the vessel (or ductus botalli) connecting together the branchial artery and vein at the root of each gill being minute. *a*, bulbus aortæ; *b*, branchial arteries; *br1*, *br2*, *br3*, the three gills (or branchiæ of each side); *bv*, the branchial veins which bring back the blood from the gills—the hindermost pair of branchial veins on each side unite to form an aortic arch (*aa*), which again unites with its fellow of the opposite side to form *da*, the descending (or dorsal) aorta. The branchial veins of the foremost gills give rise to the carotid arteries, *cc*. *o*, artery going to the orbit; *pa*, pulmonary artery; 1, 2, 3, anastomosing branches connecting together the adjacent branchial arteries and veins.

This, however, would be a mistake.

The Mud-fish or *Lepidosiren*, already referred to more than once, is furnished with both gills and lungs throughout the whole of life. On this account it has been reckoned by some naturalists to be a Fish and not a Batrachian. Its fish-nature, however, has now been tho-

roughly established, and thus the probability of the existence of lungs within the class of fishes is also established.

But what is a lung?

A lung is a sac-like structure capable of being distended with air, supplied with venous blood direct from the heart and sending arterial blood directly to it. Generally the whole of the blood from the lungs goes back to the heart directly, but in one Batrachian—the celebrated *Proteus*—a portion of the blood from the lungs finds its way not

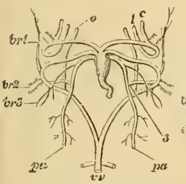

FIG. 80.

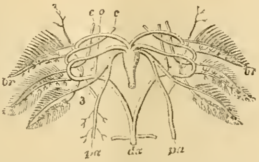

FIG. 81.

FIG. 80.—The Circulation in a Tadpole at a more advanced stage, when the gills have begun to be absorbed, the pulmonary arteries to increase, as also the connecting branches (at the root of the gills) between the branchial arteries and branchial veins.

FIG. 81.—The Circulation in a young Frog. Here the gills have been absorbed, and the blood passes directly from the heart to the head, the dorsal aorta, the lungs, and the skin,

into the heart but into vessels of the general circulation. When there is an air-sac which does not both receive blood directly from and return it directly to the heart—*i.e.* when there is no true *pulmonary* circulation—such an air-sac (whether single or double) is termed a *swim-bladder* and a structure of the kind is found in very many fishes. The swim-bladder of ordinary fishes neither receives blood directly from the heart by an artery like the pulmonary artery of higher animals, nor does it return blood directly to the heart.

The transition, however, from a lung to a swim-bladder is a graduated one. We have just seen that in *Proteus*,

Rathke). *a*, *a*, internal carotids; *b*, *b*, external carotids; *c*, *c*, common carotids; *d*, root of main aortic arch (here right); *e*, arch of the same; *f*, right subclavian (which arises from the anastomosis of the first two right primitive aortic arches); *g*, commencement of the descending aorta; *h*, *h*, left subclavian; *i*, *i*, *i*, pulmonary arteries; *k*, right, and *l*, left, rudiments of the primitive aortic arches.

FIG. 83.—Diagram representing the main arteries of a Mammal with the changes induced in the primitive condition (after H. Rathke). *a*, *b*, *c*, carotids, as before; *d*, root of main aortic arch (here left); *e*, arch of the same; *f*, commencement of descending aorta; *g*, left vertebral artery; *h*, left subclavian; *i*, right subclavian; *k*. right vertebral artery; *l*, continuation of right subclavian; *m*, pulmonary artery; *n*, remnant of left primitive aortic arch.

though blood is returned from the lungs direct to the heart, yet that not all the blood is so returned. On the other hand in another animal, *Ceratodus*, though blood is not brought to its air-sac directly (which is therefore a swim-bladder and not a lung), yet for all that blood is sent *from* it direct to the heart.

Ceratodus (or as it is locally called "flat-head") is a fish of Queensland, closely allied to *Lepidosiren*, and is a very noteworthy animal apart from and in addition to its peculiarly transitional structure as regards its air-sac.

It is, indeed, the last of an ancient race, a species of the same genus (known almost exclusively by its teeth) being found fossil in strata of oolitic and triassic date. It was discovered by the Hon. W. Foster, M.C.A. Mr. Gerard Krefft, F.L.S., Curator and Secretary of the Sydney Museum, first described and figured the animal in 1870,* and at once correctly referred it to the genus *Ceratodus*, which up to that time was supposed to be entirely extinct. Its further determination was effected by Dr. Günther.† He has conclusively shown that *Ceratodus* and *Lepidosiren* are closely allied, and thus finally brought the latter definitively within the class of Fishes, for that *Ceratodus* is a fish no one questions. It is an animal, however, of somewhat amphibious habits, as at night it leaves the brackish streams it inhabits, and wanders amongst the reeds and rushes of the adjacent flats. Vegetable substances constitute its principal food.

Ceratodus and *Lepidosiren* together afford the most remarkable evidence of the persistence of the same type of structure in the Vertebrate sub-kingdom. The group to which they both belong reaches back into the very earliest epoch, which has yet afforded us any evidence whatever of the existence of fishes; while the genus *Ceratodus* seems to have persisted unchanged from the period of the deposition of the triassic strata.

Summary.

Taking a rapid retrospect of the course we have pursued, we find that in seeking to decide as to "What is a Frog?" our inquiry into its absolute structure has made known to us an animal of peculiarly specialised and perfect organisation. This has been shown to us pre-eminently by the study of its skeleton. We have especially noted its skull, its wonderfully short vertebral column, its utterly anomalous pelvis, and its scarcely less anomalous foot. The flesh which clothes that skeleton has been seen to exhibit distinct muscles wonderfully like our own, those of the foot, indeed, exceeding ours in number, and being a very marvel of complexity. We have met with a nervous system ministered to by delicate organs of sense, and noted for the ready response to stimuli, made by even separated parts of it as evidenced by strikingly co-ordinated complex movements. We have found the circulation to be carried on by a heart which, at first sight, seems too structurally imperfect to distribute the venous and arterial blood in their respectively appropriate channels. Nevertheless, further examination has shown us that this heart is provided with a special arrangement of parts so delicately co-adjusted as to be able to act thus as efficaciously as does the heart of animals much higher in the scale. Respiration, too, we have seen provided for partly by an effective throat air-pump, partly by a peculiar activity of the cutaneous structures.

We have, moreover, found that this complex adult condition is arrived at by means of a rapid metamorphosis from an immature condition wonderfully different, indeed, but no less perfectly adapted to the life conditions of the tadpole state.

It remains now "to sum up the results" of our investigations through "a series of wider and wider comparisons" to answer, finally, as far as may be, the initial question of this little treatise.

We have, in the first place, seen that the frog belongs to an order far more distinct from cognate ordinal groups than is man's order from other orders of his class mammalia. We have also seen that the frog belongs to an order which is singularly homogeneous, and yet that the class which includes it is remarkably heterogeneous.

Again, we have found that the subordinate groups of the frog's order, families and genera, have very definite

* See "Proc. Zool." Soc 1870, p. 22.

† See "Phil. Trans." 1871, p. 511; Plates xxx. to xlii.

relations to *space*, and that the order, as a whole, is, as far as yet known, remarkably restricted as regards geological *time*.

The comparisons instituted in our survey of the frog's anatomy will enable us now to sum up resemblances; first, as regards the orders of its class, and secondly, as regards the class itself.

1. Its own order, *Anoura*, has been seen to present singular resemblances to the *Chelonia* amongst reptiles. Such are the bony plates of the back of some forms, the bony covering of the temporal fossa in others, the mode of inspiration in the adult, the armature of the jaws in the young. On the other hand, the peculiar elongated tarsus has reminded us of certain mammals, and the median Eustachian opening of *Pipa* and *Dactylethra* has suggested an affinity to crocodiles and birds. It has been plain, however, that these several likenesses, however singular and striking, are not evidences of genetic affinity.

2. The order *Urodela* may well recall to mind the *Lacertilia* amongst reptiles, with which animals the *Urodela* were actually classed by Linneus. Moreover in both groups we find a series of different species, longer and longer in body and shorter and shorter in limb. We have also seen that in both these groups an analogous complication obtains in the muscles of the legs.

3. The order *Ophiomorpha*, as has been before observed, present a general resemblance to serpents, and a special resemblance to certain short-tailed ones; though it is rather to the Amphisbenian Saurians that they may most advantageously be compared. Here, again, however, we meet with the resemblances which, though striking, do not allow themselves to be interpreted as indices of any special relationship by descent.

4. The order *Labyrinthodonta* recalls to mind, as has been said earlier, the Crocodilia amongst reptiles, of which they may be deemed as the prophetic precursors, so to speak, though certainly not the direct ancestors.

Thus the class *Batrachia*, as a whole, presents a very interesting analogy and parallelism with the class *Reptilia*. It is a parallelism, moreover, which reminds us of that which exists between the various orders of Placental mammals and the great subdivisions of the pouched or Marsupial order of mammals. We have carnivorous, insectivorous, arboreal, aquatic, herbivorous, marsupial beasts, as we have carnivorous, insectivorous, arboreal, aquatic and herbivorous placental beasts. The harmonious variations of the placental and marsupial groups thus present us with excellent instances of affinities independently evolved and not due to hereditary influence.

In a similar way it seems probable that the subdivisions (orders) of the class Batrachia, mimic, as it were quite independently, the subdivisions (orders) of the class Reptilia.

The Frogs' class, as a whole, shows as many striking affinities to some or other fishes. It does so in the possession of gills and of a branchial apparatus during one time of life at the least; a large parasphenoid in the skull; the often persistently unsegmented terminal part of the notochord; the single ventricular cavity of the heart; the presence of a *bulbus aortæ*; the development of a *nervus lateralis;* the communication between the urinary canal and the oviduct, and certain other characters of less importance.

The class *Batrachia* agrees both with fishes and reptiles in having the blood cold, more than one aortic arch, and (except in crocodiles) in not having the distinct ventricles.

The class agrees with fishes, reptiles, and birds, in having no complete diaphragm, and no corpus callosum* in the brain, and no single aorta arching over the left bronchus.

We have now arrived at the end of those considerations seemingly best suited to enable us to answer the initial question, "What is a Frog?" The requisite definition might, of course, have been given much earlier, but these inquiries have seemed necessary to enable the reader to understand the technical terms of such definition—to give them, in his eyes, a real meaning.

The Frog is a tailless, lung-breathing, branchiate vertebrate, with four limbs typically differentiated, undergoing a complete metamorphosis, and provided with teeth along margins of the upper jaw.

The course of our inquiry into the nature and affinities of the Frog has not alone served to answer the question with which this memoir opened. Incidental bearings upon deep biological problems have come before us more than once in its course, nor have all the conclusions which seem to have forced themselves upon us been totally negative.

Thus we have met with several instances of the independent origin of remarkably similar structures, such as a shielded temporal fossa and elongated tarsus, which, together with structures like the tooth of the Labyrinthodon, seem to be characters for the existence of which neither the destructive agencies of nature acting on minute oscillations of structure, nor any sexual phenomena, will account.

Again, in the life-history of the Frog, considered even purely by itself, we find a remarkable example of spontaneous transformations due to innate powers and tendencies.

When, however, this process is considered in the light derived from the curious phenomena of transformation so enigmatically presented to us by the axolotl, we have very strongly brought before us the powerful action of internal tendencies lying dormant and latent till made manifest, through the advent of conditions so obscure that as yet they have evaded the most careful and anxious scrutiny of practised adepts.

It would seem to be a negligence not here to point out, that if new forms of life—new species—arise from time to time through congenital variation, not a few of the facts herein quoted point to the probability that such forms have arisen through the evolutions of implanted potentialities definite in nature, in other words, by "specific genesis."

Again, a general survey of the different kinds of relations which the Frog has brought before us, is well calculated to impress us with the overwhelming richness and fulness of nature.

Although, from our ignorance, the natural history of many other animals well known to us may appear less replete with interest than that of the common Frog may now be, yet it cannot be doubted but that the progress of science is capable of revealing to us facts as full of instruction and of as profound a significance in the life history of almost any kind of animal whatever.

Ever fresh, ever fertile, natural history offers to our faculties a pursuit practically inexhaustible. We are not, indeed, denied the gratification of successfully exploring and satisfactorily explaining mystery after mystery, but each secret wrested by our efforts brings before us other ever new enigmas, so that though refreshed by success we need never be wearied by monotony. While we need not regard any problem as absolutely hopeless, no dread of coming to the end of our inquiries need ever chill the warmth of our zeal in the scientific cause. Some may consider such reflections justified by the phenomena presented to them by the natural history of the Common Frog.

St. George Mivart

* As to this structure see Lesson in "Elementary Anatomy," pp. 367, 375.

THE HABITS OF BEES AND WASPS*

SIR JOHN LUBBOCK, in a paper on the Social Hymenoptera (Bees, Wasps, and Ants), especially with reference to their habits, senses, and power of communication with one another, pointed out with regard to the latter, that the observations on record scarcely justify the conclusions which have been drawn from them.

* Being the substance of a paper by Sir John Lubbock, Bart., F.R.S., read before the Linnean Society on the 19th March, 1874.

Thus Messrs. Kirby and Spence say that ants have a language "not confined merely to giving intelligence of the approach or absence of danger, but co-extensive with all their other occasions for communicating their ideas to each other." The observations, however, on which this statement is based, scarcely seemed to him to be conclusive. The two Hubers, indeed, had clearly shown that ants and bees could make one another cognizant of their state of feeling, could communicate anger, danger, &c., but that was very different from the possession of a true language.

In support of the opinion that Ants and Bees possess a true language, it is usually stated that if one bee discovers a store of honey, the others are soon aware of the fact. Thus Huber says, "Wasps are also acquainted with the mode of imparting information to their companions. When a single wasp discovers a stronghold of sugar, honey, or other article of food, it returns to its nest, and brings off, in a short time, a hundred other wasps; but we are yet ignorant, if it be by visible or palpable signs, they are mutually informed of this discovery."*

This, however, does not necessarily imply the possession of any power of describing localities, or anything which could correctly be called a language. If the bees or wasps merely follow their fortunate companions, the matter is simple enough. If, on the contrary, the others are sent, the case would be very different. In order to test this, Sir John proposed to keep honey in a given place for some time, in order to satisfy himself that it would not readily be found by the bees, and then after bringing a bee to the honey, to watch whether it brought others or sent them,—the latter, of course, implying a much higher order of intelligence and power of communication.

In the first place, then, he kept some honey for some days at an open window in his sitting-room, and no bees came to it. He then brought a bee up from his hives in the garden in his hand, choosing one which was in the act of leaving the hive. He found it frightened the bees less to be brought in the hand than in a bottle, probably on account of the darkness. The bee thus brought up was then fed with honey, which it sucked with evident enjoyment for a few minutes, and then flew quietly away. But though it had given no symptom of alarm or annoyance, it did not return, nor did any other bee come to the honey. This experiment he repeated eight times, with a like result. He therefore procured one of Marriott's observatory hives, which he placed in his sitting-room. The bees had free access to the open air, but there was also a small side, or postern door, which could be opened at pleasure, and which led into the room.

This enabled him to feed and mark any particular bees, and he recounted a number of experiments from which it appeared that comparatively few bees found their own way through the postern, while of those which did so, the great majority flew to the window, and scarcely any found the honey for themselves.

Those, on the contrary, which were taken to the honey, passed backwards and forwards between it and the hive, making, on an average, five journeys in the hour. In these cases it is obvious that the bees which had found the honey did not communicate their discovery to the others; and the postern being small and on one side, few of the bees found it out for themselves. If the honey had been in an open place, no doubt the sight of their companions feasting would have attracted other bees, but in this case the honey was rather out of sight, being behind the hive entrance; and was, moreover, only accessible by the narrow and winding exit through the little postern door.

Sir John had, also, in a similar manner, watched a number of marked wasps with very similar results.

No doubt when one wasp has discovered and is visiting a supply of syrup, others are apt to come too, but he believed that they merely follow one another. He argued that if they communicated the fact, considerable numbers would at once make their appearance, but he has never found this to be the case. The frequent and regular visits which his wasps paid to the honey put out for them proves that it was very much to their taste. Yet they did not bring their companions with them. For instance, on September 19, when a marked wasp paid more than forty visits to some honey, only one other specimen came to the honey during the whole day. Both these wasps returned on the 20th, but not one other. The 21st was a hot day, and there were many wasps about the house; his honey was regularly visited by the marked wasps, but during the whole day only five others came to it.

From these and other observations of the same tendency he concludes that even if bees and wasps have the power of informing one another when they discover a store of good food, at any rate they do not habitually do so, and this seemed to him a strong reason for concluding that they are not in the habit of communicating facts. If they do not, he argues, discuss among themselves the incidents of the day, their adventures in search of food, their success and fortunes in hunting, is it not a fair inference that they have no power of doing so?

Without in any way regarding the facts now recorded as sufficient or conclusive, he thought they indicated that their communications were confined to the feelings, and that there was no power of transmitting information as to matters of fact.

When once wasps had made themselves thoroughly acquainted with their way, their movements were most regular. They spent three minutes supplying themselves with honey, and then flew straight to the nest, returning after an interval of about ten minutes, and thus making, like the bees, about five journeys an hour. During September they began in the morning at about 6 o'clock, and later when the mornings began to get cold, and continued to work without intermission till dusk. They made therefore rather more than 50 journeys in the day. In fact they were just as industrious as bees, and kept longer hours, as they began earlier in the morning. He believed that the wasps which seemed to be idling in our rooms had simply lost their way. He gave also a number of observations tending to show the difficulty which bees have in finding their way. For instance, he put a bee into a bell glass 18 inches long with a mouth $6\frac{1}{2}$ inches in diameter, turning the closed end to the window. The bee buzzed about for an hour, when, as there seemed no chance of her getting out, he released her.

Although, as everyone knows, wasps are easily startled and very much on the alert, still they are very courageous.

On one occasion one of his marked wasps had smeared herself with honey and could not fly. When this happened to a bee it was only necessary to carry her to the alighting-board, when she was soon cleaned by her comrades. But he did not know where this wasp's nest was, and could not, therefore, pursue a similar course with her. At first he was afraid she was doomed. He thought, however, that he could wash her, fully expecting, indeed, to terrify her so much that she would not return again. He therefore caught her, put her in a bottle half full of water, and shook her up and down well till the honey was washed off. He then transferred her to a dry bottle and put her in the sun. When she was dry he let her out, and she at once flew to her nest. To his surprise, in thirteen minutes she returned as if nothing had happened and continued her visits to the honey all the afternoon. The next morning she was the first to arrive.

He also had made some experiments on the behaviour of bees introduced into strange hives, which seemed to contradict the ordinary statement that strange bees are always recognised and attacked.

Another point as to which very different opinions have

* Huber, "Nat. Hist. of Ants," p. 374

been established is the use of the antennæ. Some entomologists have regarded them as olfactory organs, some as ears; the weight of authority being perhaps in favour of the latter opinion. In experimenting on his wasps and bees Sir John, to his surprise, could obtain no evidence that they heard at all. He tried them with a shrill pipe, with a whistle, with the violin, with all the sounds of which his voice was capable, doing so, moreover, within a few inches of their head, but they continued to feed without the slightest appearance of consciousness.

Lastly he recounted some observations to show that bees have the power of distinguishing colours. The relations of insects to flowers imply that the former can distinguish colour, but there had been as yet but few direct observations on the point.

THE CAVENDISH LABORATORY

THIS Laboratory, in which every facility is furnished for the prosecution of physical research, is the munificent gift of William Cavendish, Duke of Devonshire, K.G., Chancellor of the University, who has intimated his intention of presenting it complete to the University.

The building, which is now finished, was erected from the designs of W. M. Fawcett, M.A., of Jesus College, at an expense of about 10,000*l*.

The ground-floor contains a set of rooms for operations requiring great steadiness, such as the measurements of length, time, and mass, and of heat, electricity, and magnetism. A store-room, a workshop, and a battery-room are also provided on the ground-floor.

The first floor contains a spacious lecture-room with a preparation-room, a large apparatus-room, a private room for the professor, and a large working laboratory, fitted with tables standing on beams of their own, so as to be independent of the vibrations of the floor. All the tables in the building are supported in the same way, and there are in every floor small trap-doors, by means of which bodies may be suspended over the tables in the room beneath, and through which electric and other communications may be made.

The upper rooms are intended for acoustics, radiant heat, optics, electricity, and the graphic reduction of observations. There is also a dark room for photographic preparations. The air in the electric room will be kept dry by a contrivance due to Mr. Latimer Clark, and the electric machine worked in this room may be made to furnish electricity for experiments in the lecture-room.

In the tower will be erected an iron tube, which may be filled with mercury so as to measure the greater pressures to which gases and vapours are subjected in the heat-room on the ground-floor. There is also an arrangement by which the electric potential of the air at the top of the tower may be measured either in the lecture-room or in the electric-room.

The laboratory is open daily from 10 A.M. till 6 P.M. under the superintendence of the Professor of Experimental Physics, for the use of any member of the University who may desire to acquire a knowledge of experimental methods, or to take part in physical researches.

NOTES

A REUTER'S telegram from Aden, of March 23, states that the steamer *Calcutta* arrived there from Zanzibar on the previous day with the body of the late Dr. Livingstone. We fear this must be regarded as final, and as shutting out any further hope; we can only now do all possible honour to those remains which the doctor's faithful servants have so religiously preserved. A letter recently received from Zanzibar, by Mr. R. A. Laing, states that the body, after having been exposed to the sun for a month to dry, and then packed in a hollowed tree, was wrapped round with cloth, and the natives carrying it supposed it a bale of cloth, or kaniki.

H.M.S. *Challenger* arrived at Melbourne on the 17th inst.: all well. On her voyage from the Cape of Good Hope, she reached the Antarctic Circle between E. long. 70° and 80°.

IN connection with our leading article this week we see with pleasure that Mr. Mundella gave notice in the House of Commons on Monday, that "at an early day he would call attention to the Report of the Science Commissioners on National Museums, and move that, in the opinion of the House, steps should be taken to render National Museums and Galleries of Art more available for instruction for the purposes of Science and Art." We sincerely hope Mr. Mundella's motion will lead to some decided step in advance.

WE are sorry to have to announce the death of Johann Heinrich Maedler, the distinguished German astronomer, at Hanover, on March 14, at the advanced age of eighty. One of his best-known works is a Map of the Moon, of which he was the joint author with M. Beer. He was appointed Professor of Astronomy and Director of the Observatory at Dorpat in Russia about 1840, and was also the writer of various astronomical treatises:—"Popular Astronomy," Berlin, 1849; "The Existence of a Central Sun," Dorpat, 1846; "Lectures on Astronomy," Mittau, 1845–47, &c.

WE are informed that the Royal Belgian Academy has resolved to place the bust of Quetelet in the hall where its meetings are held. We believe no successor to the Directorship of the Brussels Observatory has yet been named.

AT the last meeting of the Royal Irish Academy, the Rev. Prof. Jellett resigned the office of president, and Wm. Stokes, M.D., D.C.L., F.R.S., was elected in his stead. Dr. Sullivan also resigned the secretaryship of the Academy on being made president of the Queen's College, in Cork, and Dr. E. Perceval Wright, F.L.S., was elected to the post. Dr. R. McDonnell, F.R.S., was also elected to the secretaryship of Foreign Correspondence in the place of Sir W. Wilde.

THE Professorship of Astronomy in the University of Dublin, the holder of which is also Astronomer Royal of Ireland, is now vacant by the resignation of Dr. Francis Brünnow. Since its foundation this professorship has been held by Dr. Henry Ussher (1783), Dr. John Brinkley (1790), Sir William Hamilton (1827), and Dr. Brünnow (1865). The election will be held on April 18. Rumour in Trinity College points to Prof. R. Ball, LL.D., F.R.S., as the most likely successor to Brünnow, a distinguished graduate of the University of Dublin in both pure mathematics and experimental physics. Dr. Ball acquired an extensive knowledge of astronomy during the several years that he acted as the late Lord Rosse's assistant at the Observatory at Parsonstown.

AT a numerously attended meeting of the Fellows of the Royal College of Surgeons, Ireland, held in the College Hall, Dublin, on the 13th inst., it was resolved, by a large majority, that it is not expedient for this college to take part in the proposed conjoint scheme for the examination of medical graduates in Ireland. The conjoint scheme had already been approved of by the Council of the College, by the Medical Professors and Board of Trinity College, Dublin, by the King and Queen's College of Physicians, Ireland, and by the Governors of the Apothecaries Hall.

THE circular of the Board of Trade, respecting Storm Warnings, which appeared in our last, appears to require a few additional remarks by way of explanation. The circular

speaks of an explanatory pamphlet which is now before us, and we see from it that the intention of the present system of signals is to give an indication of the *direction* of the wind to be apprehended in every case. The drum is never to be used without the cone. Its signification in Admiral FitzRoy's time was "dangerous winds from nearly opposite quarters successively;" and it accordingly gave no indication of direction *by itself*. Experience has shown that there is a much greater degree of certainty in foreseeing the *direction* than the *force* of a coming strong wind. Furthermore an attempt is made to give a degree of numerical definitiveness to the warnings, which at once admits that they are not infallible. The Committee say:—"Hitherto it has been found that at least three out of five signals of approaching storms (force upwards of 8 Beaufort scale, a 'fresh gale,') and four out of five signals of approaching strong winds (force upwards of 6 Beaufort scale, a 'strong breeze') have been fully justified." We may fairly consider this as a step in the direction of treating weather indications by the laws of exact science.

WE are glad to learn that Prof. Alluard, of Clermont-Ferraud, has at last succeeded in surmounting the various obstacles which he met with in the establishment of his proposed observatory on the Puy de Dome, at an elevation of about 1,660 metres above the surrounding country (NATURE, vol. vii. p. 481). The chief difficulty arose from the opposition of the peasant proprietors to the invasion of their rights by the construction of a road and erection of the building. M. Alluard announces that the observatory will be ready to be inaugurated in September next, and has invited his meteorological friends to visit Auvergne on that occasion.

A LARGE deposit of Moa bones has lately been discovered in a swamp at Hamilton, in Otago. Besides *Dinornis*, the swamp contains bones of *Aptornis*, *Harpagornis*, &c. The whole have been secured by the curator of the Otago Museum.

The Sedgwick Geological Prize (Cambridge) has been adjudged to J. J. Harris Teale, B.A., St. John's College. The subject for the next prize will be—"The post tertiary deposits of Cambridgeshire and their relation to deposits of the same period in the rest of East Anglia."

THE French Society of Geography has decided upon holding an International Geographical Congress at Paris in 1878. Rules and programmes will be issued shortly.

THERE has recently been concluded in connection with the Liverpool Free Public Library and Museum, a carefully arranged and excellent course of Free Lectures. This is the ninth winter course in connection with the same institution, from which we are glad to infer that these free lectures have been a success. We should like to see similar courses inaugurated in all our large towns; we believe the results would be in the highest degree beneficial. The following is a summary of the Liverpool course:—Eight Lectures on Art, by Mr. W. J. Bishop; Three Lectures on Natural History, by Mr. T. J. Moore; Six Lectures on the Chemistry of Salt, and of the Manufactures depending on it, illustrated with Specimens, Experiments, Diagrams, &c., by Mr. Edward Davies, F.C.S., &c.; Three Lectures on Geology, by Mr. G. H. Morton, F.G.S., F.R.G.S.I.; Two Lectures on Mineralogy and Mining, by Mr. F. P. Marrat, M.L.G.S.; Six Lectures on Navigation and Astronomy, by Mr. J. T. Towson, F.R.G.S.; Two Lectures on Art and Antiquities, and one on Town Window Gardens, by Mr. Charles T. Gatty; Three Lectures on the Constitutional History of England, illustrated with Historical Maps, by Mr. James Birchall; Four Readings, by Mrs. H. J. Gorst.

THE Austrian amateur navigator, Count Wilczek, writing in the *Neue Freie Presse*, says that there is no ground for apprehension as to the fate of the Austrian Polar Expedition which sailed in the *Tegetthoff*, in the year 1872, and that news will probably be received from the expedition in October or November next. Letters for members of the expedition will be despatched by the Austro-Hungarian Government by means of whaling and other vessels bound for the Arctic seas.

MESSRS. TRÜBNER and Co. have in the press and will shortly publish a treatise on "Valleys, and their Relation to Fissures, Fractures, and Faults," by G. H. Kinahan, M.R.I.A., F.R.G.S.I. This work will be dedicated by permission to His Grace the Duke of Argyll.

MR. F. C. S. ROPER, F.L.S., has published a "Supplement to the Fauna and Flora of Eastbourne, together with a list of Eastbourne Cretaceous Fossils."

MESSRS. S. W. SILVER & Co. have just published a "Handbook for Australia and New Zealand," containing a large amount of varied and useful information about the various colonies in that quarter of the world. It is accompanied by a "Seasons'-Chart of the World."

THE additions to the Zoological Society's Gardens during the last week include two Palm Squirrels (*Sciurus palmarum*) from Ceylon, presented by Capt. Forster; a Sonnerat's Jungle Fowl (*Gallus sonnerati*) from South India, presented by Mrs. White; two Tench (*Tinca vulgaris*) British, presented by Mr. W. Arnold; a Black-eared Marmoset (*Hapale penicillata*) from Brazil, presented by Mr. F. Graham; a Leadbeater's Cockatoo (*Cacatua leadbeateri*) from Australia, presented by Colonel Carington; two Boat-bills (*Cancroma cochlearia*) from South America, deposited.

CELESTIAL CHEMISTRY*

IT now and then happens in the history of the human race upon this planet, that one particular generation witnesses the most stupendous advancement of knowledge, this advancement generally coming from what one might consider an exceeding small germ of thought. You will at once call to mind several such instances. You will recollect how once a Dutchman experimenting with two spectacle-glasses produced the Telescope; and how the field of the known and the knowable has been enlarged by the invention of that wonderful instrument. Again, you recollect how once Sir Isaac Newton was in a garden and saw an apple fall, and how the germ of thought which was started in his mind by that simple incident fructified into the theory of universal gravitation. You will also acknowledge that each step of this kind has more firmly knit the universe together, has welded it into a more and more perfect whole, and has enhanced the marvellous beauty of its structure.

I think that future times will say that either this generation, or perhaps the next, is as favoured a one as that which saw the invention of the telescope or the immortal discovery of Newton: for as by the invention of the telescope the universe was almost infinitely extended; as from Newton's discovery we learned that like forces were acting in like manner everywhere; so in our time does the wonderful instrument called the Spectroscope show us that like matter is acting in like manner everywhere; so that if matter and force be not identical, then these two, namely, matter and force, may be termed the foundation stones of the universe in which we dwell.

My present object is to bring before you as well as I can some first notions which are to be got out of this general examination of all matter beyond our own planet, in its chemical relations; this examination having been rendered possible by the spectroscope.

In the first instance, before I attempt to deal with chemical ideas in relation to the heavenly bodies, I have two things to do. I must first refer to our earthly notions of chemistry, not of course in their generality, for that would be impossible in the time at my disposal, but to that side of them which touches most intimately what I shall have to say by and by; and I must also refer to the results which we have already obtained with regard to the constitution, so to speak, of terrestrial matter, as it is brought before us by the spectroscope.

* Revised from short-hand notes of a Lecture delivered at the Quebec Institute, on Tuesday, December 16, 1873.

First, then, with regard to chemistry. What is chemistry? It is a science which deals with the matter which surrounds us, and of which the whole planet and we ourselves are built up. We see everywhere around us an enormous number of apparently perfectly distinct things, some of them having vital properties, some of them lifeless, motionless; but out of this apparently infinite diversity chemistry presents us with an almost perfect simplicity. It tells us that everything which exists here is really made up of only sixty-three different things; that the whole of the animal kingdom, the vegetable kingdom, the mineral kingdom—everything—is made up of only sixty-three different substances. That is a wonderful simplification, and science always simplifies.

Now we may look upon those sixty-three elements in two distinct points of view. We may consider them in their physical relations, or we may regard them in a more purely chemical aspect. If we look upon them in relation to their physical conditions, we find that amongst them are fifty-six solids, two liquids, and five gases. If we look upon them chemically, dropping all distinctions between solids, liquids, and gases, we say that some of them are metals, some metalloids; and of some, it may be truly said that it is very difficult to place them exactly—to determine whether they are on the side of the metals or on the side of the metalloids—in the same way as the biologist finds it absolutely impossible to put his finger upon any particular part of the organic world and say, Here the vegetable, or here the animal, kingdom begins. All these chemical distinctions, then, are quite independent of physical conditions. For instance, I shall have to show you that amongst the most metallic of the metals is a gas. Again, among the metals we have a liquid—mercury; so that we have a complete chain of gas, liquid and solid among the metals, although popularly the term metal is often imagined to apply only to such solids as gold, silver, and iron. On the metalloid side, again, we have gases among them the familiar oxygen and nitrogen; we have the liquid bromine, and so on, added to other unmistakable metalloids, such as phosphorus, sulphur, carbon, and iodine, generally thought of in their solid form.

Now what are the chemist's tools by which he has brought about this marvellous simplicity, what the processes by which he carries on his operations? I answer, in the main *vibrations*. He finds the world composed of molecules in millionfold complexities, combinations, and sizes, and he acts upon these molecules by vibrations. For gross molecules he finds in heat most that he wants, but when the molecules are more delicate, then electricity is called in, and electricity does for these what heat did for the others.

Let me here endeavour to make my meaning clear. I want you to assume a long series of vibrations, long at one end of the series and short at the other. We know that heat consists of vibrations, we know that light consists of vibrations. I will also ask you to think of electricity as connected with vibrations, and I ask you further to assume these vibrations to be short. We get heat from the sun, and among these vibrations are some to which our eye is tuned. We get an immense vibration of heat from the oxyhydrogen flame, a flame the heat of which is due to the formation of the gaseous molecules of water, but we get, practically speaking, no light. Many of the electrical phenomena with which we are acquainted take place unseen, and without heat, showing they are not long-wave phenomena; others are exquisitely visible to us, because the vibrations are within our ken; but, to get associated heat, we want pressure, and with pressure we can render the oxyhydrogen flame luminous. In fact—and here let me be perfectly frank with you—I call your attention to the "*as if*"—it is *as if* we have long heat-waves at one end of a long scale, and short electricity-waves at the other, each with different functions, heat giving us with solids and liquids *visible* phemonena, because of added shorter waves, electricity giving us visible phenomena with gases and vapours, because of added longer waves; heat passing invisibly through gases, electricity passing invisibly through solids; heat bringing about chemical changes in solids and liquids, electricity bringing about similar changes in the case of gases.

Now, this being so, let us assume, for the purposes of the present statement, that the mode of motion heat, with its long waves, chiefly affects the larger molecules, that is, compound bodies, and the mode of motion electricity, whatever electricity may be, chiefly affects the smaller molecules, that is, the atoms of simple substances. We shall find, in accordance with this assumption, that if a chemist wishes to reduce the millions of compound molecules in that very compound molecule a piece of ice, he applies heat, and he gets a physical simplification, but not a chemical one, when water is produced; a still further, and exactly similar, stage is reached when this water takes the form of steam, but it is not till an enormous temperature, with its added short vibrations, or electricity, is employed, that the compound molecule breaks up into the simple things oxygen and hydrogen, unless another vibration is superadded of a molecule of another simple thing (or element) which shall aid in shaking them apart.

As instances of the action of heat, I will show you one or two experiments to indicate that in a great deal of chemical action the heat vibration requisite to bring about that simplification by means of which the simple bodies have been determined to exist as such is supplied by the chemical action itself; it is the heat of arrested motion. In other cases we have to supply the heat artificially; but also bear this in mind, that whenever we apply artificial heat the heat is none of our making. It also is the result of a chemical combination. For instance, if I take some potassium and throw it into water, that potassium will instantly burst into flame. You will see that we have a perfectly cool metal put into perfectly cool water, and, as you see, it at once takes fire in consequence of the heat of combination which has been brought about by the attraction between the potassium and the water. And if I had time I could show you that as the result of that heat-vibration thus introduced the water has been simplified, one of its constituent simple things, hydrogen, has been liberated, and I might have collected it in a bell jar.

Another illustration is to be got from a mixture of water and sulphuric acid. I have, in a test-tube, some ether, and I have the water. When I pour the water into a glass you will see that the ether in the test-tube placed in the glass will remain as if nothing had happened. But now I will pour some sulphuric acid into the water, and what happens? We get an attraction between these two things: we get a heat vibration as the result of chemical combination; and, as the result of the heat vibration produced in that manner, the water gets hot and the ether boils, the boiling point of ether being below that of water.

Here is another experiment, and I have chosen these out of many others which might have been brought before you, to show the changes brought about by heat vibrations. Here we have some bichromate of potassium, and on the application of heat it will be instantly reduced. When I say instantly reduced, probably a few seconds will be required in order to allow the heat vibration to act, and you will then have a change of colour in the solution brought about by the application of heat, artificial, so to speak, in this case, although, as I have already cautioned you, the heat of the Bunsen burner which we employ is really an effect of chemical combination.

But not only have we heat with its long waves to bring about chemical action and its result, simplification, but, as I have said, we have another agent, electricity. I have here two tubes filled with water, and a battery, and in each tube connected with this battery is a strip of platinum. The instant that the circuit is made complete you see that the water is decomposed, bubbles rise from the platinum foil, which bubbles in the one case are bubbles of hydrogen, and in the other case bubbles of the other constituent of the water—oxygen. Here you see, by means not of the long waves of heat, but by means of electricity, we bring about a complete dissociation or a complete separation of the elements of the water which originally was in these two tubes. And if we were to allow the experiment to go on a little longer, you would see that not only is there the evolution of gas in each of the tubes, but that the evolution will be greater in one tube than in the other, for this reason, that in the water there are two equivalents of hydrogen to one of oxygen.

These then are instances of simplification brought about by heat and electricity. I quit this part of the subject by the remark that the ultimate particles of an element are called atoms; that agglomerations of atoms are termed molecules; elementary molecules when the atoms are alike; compound molecules when the atoms are dissimilar. The heat-waves generally help us to get at the molecule, and electricity helps us to get at the atom; and mark, I only say *generally*. It might be universally true if all elementary atoms were alike; but on that point we must be content to say that we do not know. But I might place much evidence before you which indicates that they are vastly different. We can only study them by their vibrations;

for, as Sir Wm. Thomson has calculated, the atoms in a drop of water are so small that if the drop of water were magnified to the size of the earth, the atoms would then be seen not larger than cricket-balls or not smaller than shot.

It must be clearly understood that I here refer to the true atom and not to the atom of the chemists, the weight of which they give as the "atomic weight." It may probably turn out that this is often a molecule, sometimes a complicated one, which great heat or electricity can divide, the latter sometimes more than once. It is clear that if this be so, then the vapour densities as referred to the atomic weight will be "anomalous," because the true atom and not the chemist's atom is in question at these high temperatures.

It is now time for us to pass to the action of the spectroscope. The spectroscope, as you know, is the instrument which enables us to deal with either the refraction or the diffraction of light; that is to say, by means of refraction or diffraction we sort out the rays of any beam which we may choose to use into a spectrum, and we then study by means of that spectrum the nature and conditions of the substance which gave us the light.

And there is more than this. Not only can we deal with the giving out of light as light is being given out by this lamp, or that flame, or that gas before me, but we can equally use the absorption of light by various substances, thus studying the nature and conditions of these substances. You know very well that if this lamp, instead of having a shade of ground glass had a red one, the light that would reach your eye would be red. That simply results from the fact that the red glass stops in the main all light but the red, and allows the red to reach your eye. That then is a case of absorption, as the giving out of light by the wick of the lamp is a case of radiation.

What, then, does the spectroscope tell us with regard to the physical differences in matter? It tells us that if we have matter in a solid state, that is matter the molecules of which are large and are near together, agitated by the waves of heat, or by electricity, we get a spectrum from it of a particular kind, called a "continuous spectrum," because the spectrum is absolutely continuous, the red, yellow, orange, green, blue, violet, are all there, as you see them in the rainbow; whereas, if we deal with a gas or vapour not too dense, that is with a substance the atoms or molecules of which are smaller and further apart than in the former case, similarly agitated by electricity or, in some cases, by heat, you find that instead of having what is called a continuous spectrum, you have a spectrum in which the light is not continuous, but broken. The result of this broken condition is that we have light as it were only here and there in the spectrum. We have in fact bright lines representing a few images of the slit, instead of a rainbow band, complete from the red to the violet, representing continuous images of the slit. This you see at once enables the spectroscope to tell us the difference between the rare and the dense states of matter quite independently of what that matter may be, and whether we use radiation or absorption as the test; since a substance with a certain molecular arrangement absorbs precisely the same undulations as it gives out with the same molecular arrangement. No matter what it is, the spectroscope at once tells us whether this matter is in a gaseous or vaporous state, in which case we have lines or bands; or in a state in which the molecules are nearer together, when we get a more or less complete continuous spectrum. This at once partly explains why the almost invisible long waves of the oxyhydrogen flame soon fill a mass of the most refractory metal with waves of all lengths, until it shines out almost like the sun. It would appear that molecules or atoms, when once set vibrating by either long or short waves, perform *all* the vibrations proper to them under the conditions present.

How then about the chemical differences? Here the information afforded by the spectroscope is of a much closer character. In the first place it tells us that if you take any substance whatever in a state of gas or vapour, not only do you get bright lines, which tell you that you are dealing with a gas, but you get different bright lines for every substance, so that you not only know that you are dealing with a gas or vapour, but you know at the same time what particular gas or what particular vapour. This is qualitative spectrum analysis, as the effects depend upon the quality of the atoms or molecules present. Further, we see a change in the spectrum from simplicity to complexity, by which I mean that the lines increase in number and broaden, and that the bands become more complete and their channelled structure, where it exists, comes out better, as we pass from a low to a high pressure. This is quantitative spectrum analysis, the change depends upon the quantity of the atoms or molecules present.

Again, the spectroscope at once enables us in the main (and I say in the main, because I have already referred to the borderland between the metals and the metalloids) to differentiate quite as sharply between metals and metalloids as it does between solids and gases.

A metallic spectrum is always a line spectrum when we employ electricity to produce the vapour. Only certain metals give us line spectra at low temperatures: these are mostly monad metals which vaporise easily.

A metalloidal spectrum is only a line-spectrum when we employ electricity. Long heat-waves in their action upon the molecules only produce bands and channelled spaces. Thus the vapour of sulphur has three spectra, two to be obtained by heat, the line spectrum only being obtained by electricity..

Nor is this all. As we can distinguish the spectrum of a metal from the spectrum of a metalloid by the appearance of the spectrum, so also does the spectroscope enable us to see a difference between the spectrum of a compound molecule and an elemental molecule. Let me explain what I mean:—If we are dealing with a metallic element, we get a spectrum of a particular kind so sharply defined that when any one has once seen it, he always knows that an atom of a metal is being dealt with. In the same way when we are dealing with metalloids, the spectrum is generally so entirely distinct from the spectrum of a metal, that when you have once seen the spectrum of a metalloid produced by the long heat-waves, you will always be able to tell it again, there is no possibility of mistaking it for the spectrum of a metal. So far we have been dealing with the elemental molecules, or perchance atoms of metals and metalloids, but we can take a compound molecule. Let us take the combination between metalloids and metals, such as some of the salts of strontium—the chloride of strontium, iodide of strontium, and so on: here we have compound molecules, that is, molecules no longer built up of one substance, but of two; and the long heat-waves, although they can set them vibrating and therefore make them radiate light, do not shake them asunder as high tension electricity does.

We find that the spectroscope is perfectly competent to separate such spectra from all others, so that when we have once seen the spectrum of, say, iodide of strontium, we shall for ever afterwards know that such spectra are given by such a compound molecule as iodide of strontium. The same remark applies to the compound molecules in which oxygen enters as one of the substances. Such spectra closely resemble the spectra of the metalloids, but the bands are farther apart and lie nearer the violet as a rule, so that it is not difficult to distinguish them.

Now when we have to do with a compound molecule, that is to say, with an association of two molecules or atoms of two different chemical substances, we shall at once see that this question of vibrations instantly comes into play; for if the function of vibration, whether we deal with large molecules and long heat-waves, or small molecules and electricity, is to render more simple what in the first instance was compound, then we ought to get spectroscopic differences.

Let us again take the iodide of strontium; the spectroscope is perfectly capable of letting us see the exact effects, not of every degree of temperature which we employ, but of any great differences of temperature. We can follow each increase of temperature by observing the lines or bands which disappear, or which begin to be visible, as the case may be, as the temperature is increased. And similarly, if we have a mixture at a temperature of dissociation, and gradually bring the temperature down until association takes place, then also the spectroscope is just as competent to help us as it was before when we were dealing with an increasing temperature. We find that as the temperature decreases in the latter case, the peculiar compound spectrum to which I have already referred gets more and more visible at the same time as the elemental spectrum gets less and less visible: the order being one of strict law absolutely capable of prediction the moment you know what are the elemental lines, and the lines of any particular compound which longest resists the action of pressure.

Now this is extremely important in its bearing upon the celestial side, so to speak, of this inquiry, and therefore if you will allow me I will still further enlarge what I have said about this distinction between the metals and the metalloids.

If I take sodium vapour at a very low temperature and at the

highest temperature that I can get on the earth either by the long heat-waves or by means of electricity, I find that there is absolutely no difference whatever in the molecular arrangement of that sodium vapour at the extreme points. Spectroscopically it is absolutely the same.

Then if I take, not sodium but another element, such as iron, I find it excessively difficult, by means of the heat-waves, to shake asunder the molecules of iron and the diatomic or polyatomic molecules of iron vapour at all. But we know that by electricity non-atomic iron vapour can be got; and then we may say, at all events so far as the lines in the spectrum are concerned (I do not mean their position, but their general nature), that we get a spectrum from the vapour of iron, similar in character to that of the vapour of sodium; but the spectrum has become more complicated as we pass from the monad metal to one with a higher atomicity.

Suppose that, instead of taking a monad metal like a sodium, with its few-lined spectrum, or a metal like iron, with its high atomicity and its many-lined spectrum, we take a *metalloid;* then we find that those conditions no longer hold good. It is not too much to say that in the case of the metalloids every change of even low temperature brings about a change in the spectrum. It is perfectly true, as I have said before, that by means of electricity we can get a line-spectrum from most of the metalloids. But from the ordinary temperature to the electric spark in the case of a metalloid, instead of getting the perfect similarity that we did in the case of sodium vapour, we get an equally perfect and equally beautiful dissimilarity; so that whilst we say that in the case of sodium we only know of but one spectrum, in the case of sulphur, to take one case, we certainly know of four.

You must let me again remind you that when we employ electricity the spectra of the metalloids present exactly the same appearance as the spectra of the metallic elements, such as iron and sodium, and that it is only when we employ heat-waves that those other changes to which I have referred take place.

One word more, too, on the fundamental difference between the spectrum of a metalloid and the spectrum of a metal on the one hand, and the spectrum of a compound on the other. The metalloid has a spectrum of channelled spaces or bands, sometimes to be found in the central part, that is to say, in the green part, or thereabouts, of the spectrum, whereas in the case of the vapour of metals such as iron, and so on, we get bright lines only, not bands; and these lines increase in number generally toward the violet, while in the case of the compound molecules, such as iodide of strontium, to which I referred, we get a something which is half channelled spaces and bands, and half lines, but in all the cases I have examined, excluding oxides, they are limited to the red end of the spectrum.

Let me attempt briefly to summarise what I have stated. With electricity in the case of all elements we obtain line spectra; as we are here dealing with the most complete simplification of matter that we can attain, let us call this the *atomic spectrum.*

With heat we can obtain a continuous spectrum, from solids, liquids, and some vapours; with electricity we can even obtain a similar spectrum from dense gases. Let us call this the *molecular spectrum.*

In the case of many of the metalloids we get, between these extremes, a channelled space spectrum. Let us term this the *sub-atomic spectrum.*

In the case of some compound molecules, we get by heat in some cases, and by electricity in others, a spectrum which is dissimilar from all these. Let us call this the *compound atomic spectrum.*

J. NORMAN LOCKYER

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 19.—Preliminary Notice of Experiments concerning the Chemical Constitution of Saline Solutions, by Walter Noel Hartley, F.C.S., Demonstrator of Chemistry, King's College, London.

The author has been engaged in investigating the above subject during the last eighteen months, and his experiments being still in progress, he thinks it desirable to place the following observations on record:—

In the examination of the absorption-spectra, as seen in wedge-shaped cells, of the principal salts of cerium, cobalt, copper, chromium, didymium, nickel, palladium, and uranium, to the number of sixty different solutions, it was noticed that the tinctorial properties of the substances could be ascertained by noticing the absorption-curves and bands, so that, provided water be without chemical action, it could be foreseen what change would occur on dilution of a saturated solution.

The Effect of Heat on Absorption-spectra

When saturated solutions of coloured salts are heated to 100° C. there are (1) few cases in which no change is noticed; (2) generally the amount of light transmitted is diminished to a small extent by some of the more refrangible (the less refrangible), or both kinds of rays being obstructed; (3) there is frequently a complete difference in the nature of the transmitted light. Anhydrous salts not decomposed, hydrated compounds not dehydrated at 100° C., and salts which do not change colour on dehydration, give little or no alteration in their spectra when heated.

Solutions of hydrated salts, and most notably those of haloid compounds, do change; and the alteration is, if not identical, similar to that produced by dehydration and the action of dehydrating liquids, such as alcohol, acids, and glycerine, on the salts in crystals or solution.

A particular instance of the action of heat on an aqueous solution is that of cobalt chloride, which gives a different series of dark bands in the red part of the spectrum at different temperatures, ranging between 23° C. and 73° C. Band after band of shadow intercepts the red rays as the temperature rises, till finally nothing but the blue are transmitted. Drawings of six different spectra of this remarkable nature have been made. The changes are most marked between 33° and 53°, when the temperature may be told almost to a degree by noting the appearance of the spectrum. Though to the unaided eye cobalt bromide appears to undergo the same change, yet, as seen with the spectroscope, it is not of so curious a character, the bands being not so numerous.

With cobalt iodide a band of red light is transmitted at low temperatures; this moves towards the opposite end of the spectrum with rise of temperature until it is transferred to such a position that it consists of green rays only. In this instance the change to the eye is more striking when seen without the spectroscope, because the mixtures of red, yellow, and green rays, which are formed during the transition, give rise to very beautiful shades of brown and olive green. Thus a saturated solution at 16° C. was of a brown colour, at − 10° C. it became of a fiery red and crystals separated, at + 10° reddish brown, at 20° the same, at 35° Vandyke brown, 45° a cold brown tint with a tinge of yellowish green, at 55° a decidedly yellowish green in thin layers and yellow brown in thick, 65° greenish brown, thin layers green, 75° olive-green. An examination of this cobalt salt has shown that there are two distinct crystalline hydrates; the one formed at high temperatures has the formula $CoCl_2.2H_2O$, and is of a dark green colour; the other, which contains a much larger proportion of crystalline water, is produced at a low temperature, and its colour is generally brown, in cold weather inclining to red.

The action of heat on solutions of didymium is characterised by a broadening of the black lines seen in the spectrum, more especially of the important band in the yellow; and in the case of potassio-didymium nitrate, this is accompanied by the formation of a new line. In the case of didymium acetate, which decomposes with separation of a basic salt, the lines thickened on heating.

Thermo-chemical experiments

Regnault (Institut, 1864; "Jahresbericht," 1864, p. 99) has shown that on diluting a saturated solution of a salt, as a rule there is an absorption of heat, but in one or two cases he noticed that heat was evolved. The change in colour that takes place on the dilution of saturated solutions of cobalt iodide, cupric chloride, bromide and acetate is very remarkable. There is every likelihood that this phenomenon is due in each case to the formation of a liquid hydrate. It is impossible of belief that accompanying such a circumstance there should be no measurable development of heat; and the author's experiments have proved that in the above cases, at any rate, the heat disengaged is very considerable, amounting, for instance, on the part of cupric chloride, at least to 2,565 "units when 1 gram molecule of the crystalline salt is displaced in its minimum of water at 16° C. and brought into contact with sufficient to

make the addition of 40 Aq." These numbers only roughly approximate the truth. On diluting a solution of cobalt iodide till the red colour appears, the thermal effect must be much greater, as not only does it register several degrees on an ordinary thermometer, but it may be perceived by the hand.

The conclusions indicated by these results are obvious, but it is beyond the scope of this paper to refer to them. The writer hopes before long to complete his experiments with the view of having them communicated to the Royal Society.

Spectroscopic Observations of the Sun, by J. Norman Lockyer, F.R.S., and G. M. Seabroke, F.R.A.S.

Note on the Intracellular Development of Blood-corpuscles in Mammalia, by Edward Albert Schafer.

Linnean Society, March 19.—Dr. G. J. Allmann, F.R.S., in the chair.—The following papers were read:—Observations on Bees and Wasps, by Sir John Lubbock, Bart., F.R.S. (for an abstract of which see another column), followed by an interesting discussion in which the president, Mr. Robert Warren, Major-General Strachey, Mr. A. W. Bennett, Prof. Newton, Prof. Thiselton Dyer, Mr. D. Hanbury, Mr. Elliot of New York, and others, took part.—On *Oniscigaster wakefieldi*, a singular insect from New Zealand, belonging to the family Ephemeridæ, with notes on its aquatic conditions, by R. M'Lachlan.

Zoological Society, March 12.—Prof. Newton, F.R.S., in the chair.—The Secretary called the attention of the meeting to an important addition that had been made to the Society's collection on the 7th inst., by the acquisition of a young male Javan rhinoceros (*Rhinoceros sondaicus*) from Batavia, believed to be the first example of this rhinoceros that had ever been brought alive to Europe.—A letter was read from the Rev. S. J. Whitmee, resident at Samoa, stating that he had forwarded, through Dr. G. Bennett, of Sydney, a *Didunculus* and two curlews for the Society's collection, and giving interesting particulars concerning the habits of this bird, and another peculiar Samoan species, *Pareudiastes pacificus*.—An extract was read from a letter addressed to the Secretary by Dr. George Bennett respecting a *Didunculus*, and other birds, he had received from the Rev. Mr. Whitmee, of Samoa, intended for the Society's collection.—Dr. Günther, F.R.S., gave some details concerning the recent introduction into this country, by Lord Arthur Russell, of the Ide (*Leuciscus melanotus*, var. *orfus*).—Prof. Huxley read a memoir upon the structure of the skull and of the heart of *Menobranchus lateralis*, describing the structure of the bony skull in the osteo-cranium, and giving a full account of the primordial skull or chondrocranium, which has not hitherto been noticed. The chondrocranium was compared with that of *Proteus*, and that of larval frogs and tritons, and its essentially embryonic character was indicated. The chondrocranium was further shown to be formed by the coalescence of three distinct classes of elements which were termed *parachordal*, *pleural*, and *paraneural*. The heart was described, and the septum of the auricles was shown to be an open network allowing of free communication between the right and left auricular chambers. The structure of the *Truncus arteriosus* was compared with that observed in other amphibians.—Mr. R. B. Sharpe communicated the descriptions of two new species of birds recently procured by Mr. H. T. Ansell, of Gaboon; these were proposed to be called *Centropus anselli*, and *Dryoscopus coronatus*.

Chemical Society, March 19.—Prof. Odling, F.R.S., president, in the chair.—On Dissociation, by Prof. Dewar. The lecturer premised that as he had but little that was new to tell, he must content himself with condensing and epitomising the results of others. After briefly referring to the theories of Priestly and Hutton, he described the famous experiments of Sir James Hall, who obtained a substance identical with marble by fusing carbonate of lime under pressure. He next noticed Grove's discovery that water was decomposed at a temperature lower than that produced by the union of oxygen and hydrogen, and then explained the masterly researches of Deville on the effect of heat in causing the dissociation of carbonic anhydride, carbonic oxide, water, &c. After this the lecturer showed that in dissociation the tension of the vapour evolved is constant for a given temperature and independent of the mass, illustrating it by Debray's experiments on the decomposition of carbonate of lime at a regulated heat, and the evolution of water from certain hydrated salts. The lecture, which was illustrated with diagrams of various curves of tension, concluded with some remarks on the dissociation of the compound of hydrogen and palladium, and with a description of an apparatus devised by the speaker for ascertaining the temperature produced by the explosion of a mixture of oxygen and hydrogen under various pressures.

Meteorological Society, March 18.—Dr. R. J. Mann, president, in the chair.—Mr. R. H. Scott, F.R.S., read a paper On an attempt to establish a Relation between the Velocity of the Wind and its Force (Beaufort scale), with some remarks on anemometrical observations in general. The author stated that he considered that the existing scales of wind force were unsatisfactory. The highest pressure corresponding to force 6 of the land scale was 36 lbs. per square foot, whereas pressures of above 40 lbs. had frequently been registered. He further brought forward proofs of the irregularity in the distribution of such high pressures. He then spoke of the Beaufort scale, and pointed out some of its defects, but stated that speaking generally it might be considered to be a rough classification of the wind force, exact enough for practical purposes, and proceeding by nearly equal degrees. He had recently made experiments at Holyhead and at Yarmouth to test the velocity recorded by the anemometer at each station at the hours when the several figures of the Beaufort scale were reported. The result was a scale which agreed very closely with that given by Schott, as a deduction from theory in his discussion of the observations made by Sir F. Leopold M'Clintock in the *Fox*, and published by the Smithsonian Institution. Inasmuch as the accordance of practice with theory was very great, he proposed this scale for general adoption—

Force.	Miles per hour.	Force.	Miles per hour.
0	2·5	7	40·5
1	8	8	48·5
2	13	9	56·5
3	18	10	65
4	23	11	75
5	28	12	90
6	33·5		

The paper then went on to point out from experience gained at Holyhead, Yarmouth, and Falmouth, the very serious discrepancies which had been proved to exist in the records of velocity for the various points of the compass, especially at Yarmouth, and which showed that the influence of local situation, not only as to the contour of the country, but even the very shape and height of the observatory and the adjacent buildings, exercised a most serious influence on the correctness of the data afforded by the instruments. It therefore seemed very dangerous to reason as to the mean motion of the air over the British Isles from the anemometrical records of one or two stations, as has been done by Dove.—The next paper read was by Mr. G. J. Symons, On the Sensitiveness of Thermometers, in which he gave the results of a series of comparisons of the speed with which thermometers with bulbs of various sizes took up the true temperature to which they were exposed. Three series of thermometers were used, a set with spherical bulbs filled with mercury, and varying in diameter from a quarter to three-quarters of an inch. The result was that the small bulb took up the true temperature in about three minutes, while the large bulb took three times as long; a second set were similar in form, but filled with spirit; they were more sluggish, but the small spirit ones were more prompt than large mercurial ones. Lastly, the new patterns of spirit minimum thermometers introduced by Mr. Casella and Mr. Hicks were tested and found as sensitive as ordinary mercurial thermometers. The instruments were all examined by the Fellows at the close of the meeting.—The last paper was by Mr. R. Strachan, On the Weather of Thirteen Autumns.

Royal Astronomical Society, March 13.—Prof. Adams, F.R.S., president, in the chair.—On an occultation of Neptune observed at Walthamstow on April 24, by Mr. Talmage. The planet was seen to skirt along the moon's limb, and was only occulted for a few seconds. The occultation was also watched for at Greenwich by Mr. Criswick, and although the difference of latitude only amounts to a few miles, the planet was never lost sight of.—On a remarkable structure visible upon the photographs of the solar eclipse of December 12, 1871, by Mr. Ranyard. In viewing the photographs by transmitted light a minute partially transparent spot can be traced at a height of about 9′ from the eastern limb on all the negatives of Lord Lindsay's series, and on four out of the six negatives of Col. Tennant's series. It appears to occupy identically the same place with regard to the dark details of the corona in all the photographs, and cannot therefore be due to any reflection within the camera, for the position of the corona

is shifted upon the different plates. On first making the discovery, he had been inclined to think that it must be due to a star seen through the corona, but on further reflection he had been obliged to abandon that idea, for a star would have been represented by a dark or opaque point, whereas this must be due to an object darker than the corona, apparently hiding or cutting out some of its light. On a closer examination of the negatives, with suitable lights, three partially transparent circular arcs concentric with the bright point were detected above it. Such forms are totally different from the corona structure visible on other parts of the plate, and there seemed no alternative but to suppose that they were due to some partially opaque body situated between us and the sun, cutting out or partially intercepting the light of the corona. The structure is similar to that which has often been observed in the nuclei and concentric comæ of comets, and Mr. Ranyard thought that it did not seem unreasonable to suppose that this was really a photograph of a faint though large comet near to perihelion. Mr. Christie said that he had examined the negatives and he did not think there could be any doubt about the existence of the structure. It was distinctly to be traced on Lord Lindsay's series, and also on those taken 120 miles away at Ootacamund by Col. Tennant.

Entomological Society, March 16.—Sir Sidney Smith Saunders, president, in the chair.—Mr. Champion exhibited specimens of *Euryporus picipes* taken near Chatham.—Mr. Edward Saunders exhibited a box of *Buprestidæ* collected by Prof. Semper in the Philippine Islands; and read some notes and descriptions of the new species.—A paper was communicated by Prof. Westwood on several additional species of *Lucanidæ* in the collection of Major F. J. Sidney Parry.

Geologists' Association, March 6.—Prof. Morris, F.G.S., vice-president, in the chair.—On the geology of the Nottingham district, by the Rev. A. Irving, F.G.S. The district under aonsideration comprises coal-measures, Permian, Bunter, Keuper, and Lias rocks—a border-land between the Palæozoic and Mesozoic epochs. No apparent unconformability exists between the Permian and Triassic series here; while that between the Permian and coal-measures is enormous. (1) *Coal Measures.* There are seven seams of coal at present workable in this field, with many more of inferior quality. The enormous unconformability between the coal-measures and the Permian is shown by the fact that at the Shire Oak Colliery near Worksop, 1,300 ft. of coal-measures are passed through before the "top-hard" is reached, whilst at Stretley, twenty miles to the south, the magnesian limestone rests directly (according to Mr. G. Fowler, C.E.) upon the "top-hard" seam. (2) *The Permian.*—The great unconformability between the Permian rocks and the coal-measures is rendered more significant by the absence of the Lower Red Sandstone (Rothliegende), whilst there are clear proofs of continuous deposition of the Permian and Lower Bunter. In this area stratigraphical evidence points to the Permian and Bunter as but portions of one great unbroken sequence of rocks deposited upon highly disturbed and denuded coal-measures. (3) The *Bunter.*—The Lower Mottled Sandstone is nowhere more than 100ft. thick. The Himlack stone exhibits the junction of the Lower and Middle Bunter. It is marked by unconformability. A bed of calcareous grit and breccia forms the basement of the pebble beds, or Middle Bunter. This is evidently a shore formation. The author concluded, from its composition and from the general prevalence of current bedding, that it occupied an area of deposition subject to shifting currents, but protected from the open ocean. (4) *Keuper.*—Two sections were given where the "water-stones," consisting of alternating beds of sandstone and marls, are seen resting upon the eroded surface of the bunter. In each case the junction is marked by a bed of highly calcareous breccia; and there is unconformability between the two formations. Footprints of *Cheirotherium* have been observed at Castle Donnington, and recently by the author at Colwick, near Nottingham. Ripple marks, &c., are also commonly met with. (5) The *Rhætic beds.*—The black paper shales were discovered by Mr. Etheridge a short time ago at Elton; there also the author has found a portion of the bone-bed. (6) The *Lias* may be observed capping the hills on the south side of the Trent Valley. Belvoir Castle crowns an escarpement of the Middle Lias (marlstone), abounding in *Rhync. tetrahedra* and *Ter. punctata.* (7) *Drift and Alluvium.*—The greater part of the former appears to have been long since carried down into the valley of the Trent, where extensive gravel-pits are worked, as *e.g.* at Saveley and Beeston.

PARIS

Academy of Sciences, March 16.—M. Bertrand in the chair. The following communications were read:—Note on the employment of flexible laminæ for the tracing of arcs with curvature of large diameter, by M. Resal.—Researches on symmetrical isomerism and on the four tartaric acids, by MM. Berthelot and Jungfleisch. The authors have determined the heat of solution of dextro-tartaric acid, lævo-tartaric acid, racemic acid, and inactive tartaric acid. The authors think it probable from their researches that water decomposes the inactive acid into its two active constituents during the act of solution.—On the crystalline hydrates of sulphuric acid, by M. Berthelot; also a thermo-chemical communication.—Experimental researches leading to a determination of the sun's temperature: a letter from P. Secchi to the perpetual secretary. The author has compared the solar radiation with that of the electric arc from a battery of 50 Bunsen's elements, using for this purpose his "thermo-heliometer." After making necessary corrections for atmospheric absorption the result obtained is 133780°, but the author considers this number only an approximation, and considers it possible that it may have to be raised to 169680°.—Report of the geodesic work relating to the new determination of the French meridian, by M. Elie de Beaumont.—Memoir on the swim-bladder from the point of view of station and locomotion, by M. A. Moreau.—On an application of the theory of substitutions to linear differential equations, by M. C. Jordan.—On the heat of combustion of different varieties of red phosphorus; a note by MM. Troost and Hautefeuille.—On the conditions which determine the movements of chlorophyll granules in the cells of *Elodea canadensis*; note by M. E. Prillieux. By a microscopical examination the author has sought to distinguish clearly in the example chosen the movements which are affected by light from those produced by lesion of the tissues during the act of preparation for microscopic examination.—The blocks and rolled flints in the Red Sandstone of the drift of Saint-Brieuc; note by M. T. Héna. These flints appear to have been brought from Erquy, 24 kilometres to the north-east of Saint-Brieuc by means of floating ice.—On the laws of the plane distribution of pressures in the interior of the isotropic bodies in the state of limited equilibrium; note by M. J. Bossinesq.—On the friction of glaciers and the erosion of valleys, by M. C. Grad. The author expresses his belief that neither the Alpine valleys, the Italian and Swiss lakes, nor the fjords of Norway and Greenland owe their origin to glacial erosion.—Chemical nature of the sulphide of iron (troïlite) contained in meteoric irons, by M. S. Meunier. A reiteration of the view, formerly expressed by the author, that this substance is a variety of pyrrhotine (Fe_7S_8) and not simply a ferrous sulphide (FeS).—On a phosphate of cerium containing fluorine, by M. F. Radominski. This mineral contains cerium, lanthanum and didymium, calcium, magnesium, iron, fluorine, phosphoric acid and traces of water. It was found near Fahlun in Sweden. During the meeting M. Gosselin was elected into the section of medicine and surgery to supply the vacancy caused by the death of M. Nelaton.

MARY SOMERVILLE

Personal Recollections, from Early Life to Old Age, of Mary Somerville, with Selections from her Correspondence. By her daughter, Martha Somerville. (London: John Murray, Albemarle Street, 1873.)

IT would have been a lasting blot upon the biographers of our time if such an illustrious woman as Mary Somerville—a woman unique, or almost unique from one point of view, though so beautifully womanly from others—had been allowed to pass from among us without a satisfactory memorial of her characteristic thoughts, conversation, and domestic life.

The "Personal Recollections of Mary Somerville" will not satisfy those readers who may have hoped to find in the autobiography of the author of the "Mechanism of the Heavens" and the "Connection of the Physical Sciences" any special expositions of Science or practical hints for a successful method of scientific training. The studied care with which Mrs. Somerville avoided bringing scientific questions prominently forward in conversation has been rigidly preserved in the story of her life, where little or nothing is said of the processes by which she attained so exceptional and distinguished a place in the world of Science, and only passing references are made to the extraordinary success that attended her self-acquired knowledge.

As the record of a life in which the fulfilment of all the natural and conventional claims upon a woman's time was combined with practical and theoretical pre-eminence in the most abstruse departments of physical inquiry, no book can, however, be more interesting and suggestive than this volume, in which the personal recollections of Mary Somerville are noted down for us by her own hand and that of her daughter. The story of her life has, moreover, the special interest that it may, with perhaps equal justice, be made to yield arguments for and against the claims advanced for women's equality to men in intellectual capacity. The champions of such pretensions may well point with triumph to her achievements in the higher branches of analytical geometry. Where, indeed, could another instance be found of a person who, after having had to ask, at the age of 16, the meaning of "the *x's* and *y's* mixed with strange lines," which first excited her notice in the pages of a magazine of fashion, should unaided—for she was in all essentials a self-taught mathematician—have been able to begin her career as an author by producing a work like the "Mechanism of the Heavens," which still ranks as the best exposition that we possess of Laplace's "Mécanique celeste"?

The approval which this work won from the first mathematicians and physicists of the day seems to have surprised no one more thoroughly than the writer herself, who had carried on her studies with such unostentatious industry within her own home, that she was scarcely conscious how exceptional were her attainments. And it may be fairly said of her that by the publication of the "Mechanism of the Heavens," in 1831, she suddenly awoke, at the advanced age of 51, to find herself famous, the one woman of her time, and perhaps of all times, for whatever may be the advantages which are now happily being placed within the reach of women for benefiting by high scientific training, we can scarcely expect to meet with many Mary Somervilles. Her genius was unique of its kind, and wholly exceptional, and this fact seems to have been frankly and generously admitted by all who came in contact with her, who were capable of measuring the depths of her knowledge. But so successfully did she conceal her learning under a delicate feminine exterior, a shy manner, and the practical qualities of an efficient mistress of a household, coupled with the graceful, artistic accomplishments of an elegant woman of the world, that ordinary visitors, who had sought her as a prodigy, came away disappointed that she looked and behaved like any other materfamilias, and talked just like other people. No one, therefore, could possibly have afforded a stronger refutation of the axiom, almost universally upheld half a century ago, that scientific acquirements of a high order are wholly incompatible with the proper exercise of the natural and ascribed functions of a woman's destiny. And accordingly the name of Mary Somerville has always been a tower of strength to the promoters of woman's emancipation from the enactments established by man for her exclusion from the enjoyment of the various social, legal, intellectual, and other privileges, of which he has so long had the virtual monopoly.

Her fame did not rest only on her first book—in which she had verified Laplace's own testimony, that she was the only woman who had ever read his works, which, moreover, were not understood by twenty men in France as well as she understood them—for the list of her writings includes, in addition to those more generally known from their semi-popular form as the "Connection of the Physical Sciences," "Physical Geography," &c.; monographs on the Analytical Attraction of Spheroids, the Form and Rotation of the Earth, the Tides of the Ocean and Atmosphere, and, besides many others of equally abstruse nature, a treatise of 246 pages on Curves and Surfaces of the Second and Higher Orders, which she herself tells us she wrote *con amore*, to fill up her morning-hours while spending her winter in Southern Italy. A truly marvellous *catalogue raisonné* of the results of a woman's knowledge and industry!

It is impossible to speak too highly of the sympathy and hearty recognition of the value of her labours that Mrs. Somerville received from all the most eminent of her contemporaries. In France, Laplace, La Croix, Biot Poisson, Arago, Ampère, and many others welcomed her as one of themselves; in England she enjoyed the intimate friendship of the Herschels, Lord Brougham, Professors Whewell, Peacock, Babbage, Sedgwick, and Brewster, and others pre-eminent in science; and surely no greater tribute could have been paid to the exceptional intellectual superiority of Mary Somerville than that rendered by the University of Cambridge when, at the earnest recommendation of Profs. Whewell and Peacock, her "Mechanism of the Heavens" was introduced into the University studies as "essential to those students who aspire to the highest places in the examinations."

It would not be easy to over-estimate the extent and degree in which Mrs. Somerville's acquirements differed from those of women generally at that period; but then

it must be admitted that it is precisely through this exceptional character of her attainments that her case may be adduced in proof of the rule that women are not by nature adapted for studies which involve the higher processes of induction and analysis. If such powers as hers had been more generally granted to women, why is she the only woman on record amongst us who has exhibited them?

There was nothing exceptional in her bringing up, or her opportunities. In fact, no woman of her time and station could have had a more typical experience of life than she had. She was born nearly a century ago, in 1780, and spent her childhood and youth in Scotland, within an ordinary circle of the upper middle-class society of her age and country, and therefore very closely circumscribed by lines of defence against innovations and social changes of any kind. Her father, Captain Fairfax (a brave officer who commanded the *Repulse* during the war), received the news of her having taught herself the first six books of Euclid with the remark—"We must put a stop to this, or we shall have Mary in a strait-jacket one of these days. There was 'X.,' who went raving mad about the longitude!" This gallant captain was, moreover, a genuine good Tory, who took decided views in regard to all questions involving a departure from established precedents, and when his young daughter ventured to express her admiration for the short-cut hair, which was then the badge of a Liberal in politics, he exclaimed, "By G—, when a man cuts off his queue the head should go with it." Her mother, who found all her intellectual cravings amply satisfied with the reading of her Bible, a volume of sermons, and a stray copy of a newspaper, fully concurred in her husband's views of the education suited to young women, and was at great pains to thwart her daughter's unladylike taste for pursuits regarded at the time as the exclusive privileges of men, and to keep her mind and hands closely fettered by the bonds of a household possessed of very limited pecuniary means. The parents of the future authoress of the "Connection of the Physical Sciences" did not, therefore, afford her special facilities for mastering any of those higher branches of knowledge for which she seems to have had an instinctive yearning almost before she knew their names. Indeed, at the age of 10, Mary Fairfax was still a little ignorant savage, running wild over the hills and braes of Burntisland, and scarcely knowing her letters; yet before she was 13 she had surreptitiously possessed herself of some of her brother's books and taught herself Latin enough to construe "Cæsar's Commentaries." At that time she scarcely knew the simplest processes of arithmetic, but at the age of 17 the possession of a copy of "Bonnycastle's Algebra," procured for her by her uncle and future father-in-law, Dr. Sutherland—the only one of her relations who did not absolutely oppose her efforts to acquire knowledge—enabled her to solve the mystery of the X's and Y's; and from that hour till the day of her death, mathematics, in one shape or other, may be said to have formed part of her daily existence. For more than half a century they were the staple occupation of her morning hours when the duties of her house and family had been disposed of; at a very advanced age she began and mastered the study of Quaternions, and other forms of modern mathematics, and at 89 she "still retained facility in the calculus."

The restless activity of her intellect had indeed never slumbered. When she received her first lessons in painting and music, she had begun at once to try and trace out the scientific principles on which these arts are based, and never rested till she had gained some knowledge of the laws of perspective and of the theory of colour, and had learnt to tune her own instruments. In later years she may be said to have been always in the van of discovery—not indeed as an originator but as the readiest and aptest of students—and from the time when Young showed her how he conducted the experiments by which he claimed to have discovered the undulatory theory of light, and Wollaston made her one of the very first witnesses of the seven dark lines crossing the solar spectrum, whose detection laid the basis of some of the most wonderful cosmical discoveries of this or any age, Mary Somerville, to the last day of her long life of nearly 92 years, followed with quick and appreciative understanding every step in the advance of modern research. Age could not quench the fire of her intellect, and even in her 92nd year, when the Blue Peter, as she quaintly remarks, had long been flying at her foremast, and she had soon to expect the signal for sailing, she could interest herself in the phenomena of volcanic eruption, speculate on their effects, and follow with lively sympathy the progress of scientific inquiry, and the issues of passing events.

In reading the personal recollections of this wonderful woman nothing strikes one more than the ordinary and even commonplace conditions under which her great intellect advanced to maturity. In her case the only exceptional features were her natural gifts and her perseverance in cultivating them; and this is precisely the point that should not be lost sight of. Mary Somerville will always present a noble instance of what a woman has been capable of achieving, but it would be straining the argument too far to say that we are justified from her special case to draw general conclusions in regard to women's aptitude for the study of the higher forms of physical science.

EXTINCT VERTEBRATE FAUNA OF THE UNITED STATES

Contributions to the Extinct Vertebrate Fauna of the Western Territories of the United States. By Prof. Joseph Leidy. (Government Printing Office, Washington.)

THIS important volume is the first of five which are to form the "Report of the United States Geological Survey," and it will be supplemented by a memoir, embracing the same subjects, by Prof. Cope.

The large field for palæontological work recently opened up in the Western Territory of the United States has been as fruitful in the introduction of new and unexpected forms of extinct vertebrate life, as that so ably worked out by Cuvier, the Paris basin. By the establishment of a military station at Fort Bridger, opportunities have been afforded to geologists, which the offensive attitude of the Indian tribes had previously deferred, rendering inaccessible a district, the richness of whose past fauna must have been as remarkable as is its present desolation.

Fort Bridger is a military post about 100 miles E.N.E. of Great Salt Lake City, in the south-west corner of the Wyoming Territory. The valley in which it is situated stands nearly 7,000 ft. above the level of the sea at the base of the Uintah Mountains, which form its southern boundary; the Wind River Range defining it on the north-east, and the Wahsatch Mountains on the west separating it from the Great Salt Lake. The enclosed plain is evidently the remains of an extensive fresh-water lake, which in the Eocene period must have abounded with animal life, and whose borders must have been the haunts of animals, both huge and small, which lived and died by its marshy banks. Green River now runs through the plain, and it, with its smaller tributaries, by cutting up the easily eroded deposit, produces a scenery of a most peculiar character, consisting of flat-topped hills and cliffs, with perpendicular sides, and often most grotesque proportions. Those of the water-courses which do not dry up during the summer months are fringed with vegetation, such as cotton-wood, willow and aspen trees, but most of the country is treeless and barren, reminding the spectator more ot the ruins of a colossal city, than of any other existing scenery.

The flat-topped hills, table-lands, and scarp-rocks are termed "buttes," and the fossils are generally found at their bases, having fallen there from the gradual atmospheric disintegration of their sides, along with the *débris* of the deposits. The fossils consist mostly of the bones and teeth of vertebrata, together with lacustrine shells. The bones are generally black or brownish, sometimes yellowish; they are generally distorted and much broken, except the small ones, such as those of the carpus and tarsus. They do not withstand the action of the air at all well.

The remains of mammals, which are very abundant, are mostly of genera which are not found elsewhere. Several, however, approach those of the Paris tertiary basin. The odd-toed Ungulata, or Perissodactyla, are particularly numerous, whilst even-toed Ungulate or Artiodactyla are as remarkably few. True Proboscidians are not found, but if Prof. Marsh is correct in placing Dinoceras in an order by itself, animals equally huge, of an independent type, were far from uncommon. Most of the other mammalian orders are most probably represented, though much has yet to be done in the identification of specimens.

Prof. Leidy has not yet seen any remains of bird, but we, some time ago, called attention to Prof. Marsh's discovery of *Odontornis*, a bird with well-developed teeth in both jaws; quite different from *Odontopteryx* of Owen, which has not true teeth, but teeth-like processes of the jaws.

The remains of turtles are most numerous; many of them were aquatic, and some belong to genera which cannot be distinguished from those now existing. What is also particularly interesting to note is that the remains of Crocodilia, which are not very abundant, are all derived from species of true *Crocodilus*, the old-world form, with the lower so-called "canines" fitting into a notch in the upper jaw, and not from *Alligator*, the genus which is now found in the Mississippi and its neighbourhood, with the lower "canine" fitting into a maxillary socket.

From the large amount of material which has passed through his hands, most of which is deposited in the Museum of the Academy of Natural Science of Philadelphia, there are some types of animals which Prof. Leidy has been able to work out in sufficient detail to make his results of general interest. Perhaps the most complete of these is *Palæosyops*, a perissodactylate Ungulate, of about the size of the Tapir, portions of the bones and nearly complete sets of the teeth of which have been several times discovered. The dental formula was complete, the typical forty-four teeth being present, all close together in the usual numbers, namely i. $\frac{3-3}{3-3}$, c. $\frac{1-1}{1-1}$, p.m. $\frac{4-4}{4-4}$, m. $\frac{3-3}{3-3} = 44$. The canines were peculiarly large, having much the same proportions as in an average carnivorous animal, like the bear. The molars have a resemblance to *Palæotherium*, the inner lobes of the crowns of the upper molars being, however, more completely isolated. There was a third trochanter to the femur, and three toes, as in the Tapir, were present on the hind feet. *Palæosyops paludosus* is the most common species. It is not known whether the neck was long and curved, as that of *Palæotherium* is now found to have been, or whether it was short and straight, as in the Tapirs. *Limnohyus* is a closely allied genus, named by Prof. Marsh.

Another perissodactylate, *Hyrachyus*, closely resembles *Lophiodon* of France, but has an extra premolar in the lower jaw, and a lobe less in the last lower true molar.

Perhaps *Trogosus* is one of the most interesting of the extinct mammals from the "Mauvaises Terres." It is also perissodactylate, and slightly smaller than the common pig. Its dentition would almost lead to the idea that the long-missing form which may be supposed to connect the Ungulata with the Rodentia, has at last been discovered; for with the usual complement of molar teeth there are no canines, and a huge pair of rodent-like incisors, which, in the lower jaw at least, had an intermediate pair of very small teeth. The large incisors had *persistent pulps*, and were formed in part of a circle; they wore down obliquely, in the same way as in the Cavies; were grooved longitudinally, somewhat as in *Aulacodus*, and were covered with enamel on the anterior surfaces only.

It is not to be wondered at, when small fragments of the skull of an animal so unknown and aberrant as *Uintatherium* (or *Dinoceras* of Marsh) were obtained, that each piece should have been referred to a separate genus and species, and Prof. Leidy, in the latter part of his memoir, puts together, as parts of *Uintatherium*, the tusks, horn-cores, &c., as parts of one and the same animal, which he had considered to be portions of different animals in the earlier part of his work, and which he had no reason for associating until Prof. Marsh had described the complete skull of *Dinoceras mirabilis*, which we figured some time ago. As we also mentioned at the time, Prof. Cope has also named this genus *Eobasileus* and *Loxolophodon*.

Besides the above mentioned, most characteristic forms, some from other territory strata west of the Mississippi River, are described—ungulate, rodent, and carnivorous—many of which are intimately related to those of the Paris basin, and throw further light on them. Prof. Leidy also

figures and describes several of the Chelonia and other reptiles which come from the same locality.

The above notice of the results arrived at by American men of Science show that they deserve the careful study of English palæontolologists and geologists, as they have already thrown great light on the fauna of the Tertiary period, and give promise of adding much more to our knowledge of that epoch, so important to the student of the anatomy and classification of the higher vertebrata.

OUR BOOK SHELF

The Laboratory Guide, a Manual of Practical Chemistry for Colleges and Schools, specially arranged for Agricultural Students. By Arthur Herbert Church, M.A. (London: Van Voorst, 1874).

TEACHERS of chemistry will be glad to welcome the third edition of Prof. Church's "Guide," to which much new matter has been added. Being specially adapted for students of agricultural chemistry, the book is necessarily somewhat limited in its scope, but the amount of information conveyed within the small compass of 215 pages is very great, and is moreover lucid and accurate. The book is divided into three portions, the first treating of a chemical manipulation, the second of qualitative analysis, and the third of quantitative analysis. The author's preliminary remarks upon manipulation are excellent, and should be graven upon the mind of every chemical student. In the "Introduction" we are told that the student "must never forget that the experiment is the means, not the end. . . . . Merely to make a coloured precipitate or a flash of bright flame is not the end of experimenting."

These remarks are much to the purpose, and we commend them to the notice of chemists of older growth, as well as to beginners. The sudden introduction of equations on p. 8 without any previous explanation of the meaning of symbolic formulæ appears somewhat unsystematic, but the student is recommended by Prof. Church to attend some course of lectures on inorganic chemistry, and to study the corresponding chapters in Roscoe's Chemistry, at the same time that he is working through the "Guide." As the "Guide" is at present arranged, the student will find this absolutely necessary. The classification of the metals adopted by the author calls for remark—iron and manganese are classed as dyads and aluminium as a triad. Further on it is explained that this last metal is only a pseudo-triad, being in reality a tetrad. Why not class it with the tetrads at once? Hexad metals and pentad metals are ignored altogether, although manganese forms a hexafluoride, arsenic, and antimony, penta-haloid compounds, &c. We must protest also against the use of the words "vinculant," "vinculance," "univinculant," &c. No advantage is likely to accrue to the science from this new phraseology, and the terms "atomicity," "monatomic," "diatomic," &c., which are in general use, express the idea perfectly. The tables for qualitative analysis differ but little from those generally adopted. The quantitative processes for the analysis of natural products, soils, foods, &c., will be found very useful. In addition to the direct benefit arising from the issue of books like the present, there is an indirect benefit for which we ought to be also indebted to Prof. Church—we refer to the expulsion from the market of hastily compiled and inaccurate works by so-called "Science Teachers," such as it has been our duty to condemn on former occasions.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Prof. Tait and Mr. Spencer

As is shown by the passage from his *Thermodynamics* which he re-quotes, Prof. Tait holds that "Natural philosophy is an experimental, and not an intuitive science. No *à priori* reasoning can conduct us demonstratively to a single physical truth."

I hold, on the contrary, that as there are *à priori* mathematical truths, the consciousness of which results, not from our individual experiences, but from the organized and inherited effects of ancestral experiences, received throughout an immeasurable past; so are there *à priori* physical truths, our consciousness of which has a like origin.

I have endeavoured to show that Prof. Tait himself, by saying of physical axioms that the appropriately-cultivated intelligence sees "*at once*" their "*necessary* truth," tacitly classes them with mathematical axioms, of which this self-evidence is also the recognised character. Further, I have contended that the laws of motion are *à priori* truths of this kind; are enunciated by Newton as such; are adopted from him by Prof. Tait; and are not furnished by Prof. Tait with any such experimental proofs as he asserts are needful for the establishment of physical truths. And I have gone on to show that no experimental proofs of them are possible—that every supposed proof, whether derived from terrestrial phenomena or from celestial phenomena, involves a *petitio principii.*

In the course of the discussion I have examined the reason Prof. Tait gives for asserting that the laws of motion are not to be accepted as valid *à priori.* The reason is that "as the properties of matter might have been such as to render a totally different set of laws axiomatic, *these laws must be considered as resting on convictions drawn from observation and experiment, and not on intuitive perception.*"

The worth of this reason I have tested by asking the origin of Prof. Tait's professed knowledge that "the properties of matter might have been" other than they are. Here is the passage:—

"It will suffice if I examine the nature of this proposition that 'the properties of matter *might have been*' other than they are. Does it express an experimentally-ascertained truth? If so, I invite Prof. Tait to describe the experiments. Is it an intuition? If so, then along with doubt of an intuitive belief concerning things *as they are*, there goes confidence in an intuitive belief concerning things *as they are not.* Is it an hypothesis? If so, the implication is that a cognition of which the negation is inconceivable (for an axiom is such) may be discredited by inference from that which is not a cognition at all, but simply a supposition. Does the reviewer [a critic whose attack I was answering] admit that no conclusion can have a validity greater than is possessed by its premises? or will he say that the trustworthiness of cognitions increases in proportion as they are the more inferential? Be his answer what it may, I shall take it as unquestionable that nothing concluded can have a warrant higher than that from which it is concluded, though it may have a lower. Now the elements of the proposition before us are these:—*As* 'the properties of matter might have been such as to render a totally different set of laws axiomatic' [*therefore*] 'these laws [now in force] must be considered as resting . . . not on intuitive perception:' that is, the intuitions in which these laws are recognised, must not be held authoritative. Here the cognition posited as premiss, is that the properties of matter might have been other than they are; and the conclusion is that our intuitions relative to existing properties are uncertain. Hence, if this conclusion is valid, it is valid because the cognition or intuition respecting what might have been, is more trustworthy than the cognition or intuition respecting what is! Scepticism respecting the deliverances of consciousness about things as they are is based upon faith in a deliverance of consciousness about things as they are not!"

From this passage Prof. Tait has quoted a small part which, standing by itself, appears somewhat strange; but which ceases to appear strange when read along with the rest. In seeking the authority which Prof. Tait has for asserting that "the properties of matter might have been" other than they are, I have tried all possible suppositions; and as he professes to have faith only in experimentally-ascertained truths, I have asked whether this is one; by way of showing, unmistakeably, that in the absence of experimental warrant he must admit it to be, if not a mere hypothesis, then an intuition. Whence results the incongruity I have pointed out.

Prof. Tait says this argument of mine reminds him of a student whose conceptions of algebraic processes were shown by asking—"But what if x should turn out after all *not* to be the unknown quantity?" His imagination suggests to Prof. Tait an analogy too remote for me to perceive; and one which I think few will

follow him in perceiving. It seems to me that in this case "the unknown quantity" is the application of his story.

I have to add that Prof. Tait's letter gives the erroneous impression that I have made a gratuitous assault upon his views. Contrariwise, I have said respecting them no more than is needful in self-defence. A critic who thought me greatly in need of instruction respecting the nature of proof and the warrants we have for our ultimate scientific beliefs, quoted, for my benefit, the foregoing passage from Prof. Tait; and he did this in a manner implying that when he had told me what Prof. Tait said, there remained for me no alternative but to abandon my position. As I did not coincide in his general estimate of Prof. Tait's *dicta*, and as this particular question is one of some philosophical interest, I thought it worth while to justify my own belief, and, in so doing, was obliged to assail that of Prof. Tait.

In Prof. Tait's desire to avoid controversy I quite sympathise. Though sometimes scarcely avoidable, it entails, as I know too well, a grievous loss of time. But as Prof. Tait decided not to answer, I think it would have been better to keep silence absolutely, rather than to try and dispose of the matter by tearing a sentence from its context, and telling, *à propos* of it, a story not to the point.

Athenæum Club, March 30 HERBERT SPENCER

Herbert Spencer versus Sir I. Newton

PROF. TAIT is not the only one who has to complain of hard treatment in the pamphlet by Mr. Herbert Spencer, referred to in the Professor's letter of last week. As the unlucky author of the obnoxious criticism that gave rise to the pamphlet in question, I of course come in for a lion's share of the abuse; but neither Prof. Tait nor myself are, after all, treated so cruelly as is Newton, who, though his life was spent in maintaining the experimental character of all physical science, is cited as an authority for the *à priori* character of the most important of all physical truths—the well-known Three Laws of Motion.

Mr. Spencer had asserted that these Laws of Motion are *à priori* truths, and had supported this statement by alleging that Newton gave no proof of them, and therefore intended them to be so regarded. After sheltering myself under the authority of Professors Tait and Thomson, I answered that "the whole of the *Principia* was the proof," whereon Mr. Spencer replies as follows:—

"I have first to point out that here, as before, the reviewer escapes by raising a new issue. I did not ask what he thinks about the *Principia* and the proof of the laws of motion by it; nor did I ask whether others, at this day, hold the assertion of these laws to be justified mainly by the evidence the solar system affords. I asked what Newton thought. The reviewer had represented the belief that the second law of motion is knowable *à priori* as too absurd even for me openly to enunciate. I pointed out that since Newton enunciates it openly under the title of an axiom, and offers no proof whatever of it, he did explicitly what I am blamed for doing implicitly. And thereupon I invited the reviewer to say what he thought of Newton. Instead of answering, he gives me his opinion to the effect that the laws of motion are proved true by the truth of the *Principia* deduced from them. Of this hereafter. My present purpose is to show that Newton did not say this, and gave every indication of thinking the contrary. He does not call the laws of motion 'hypotheses;' he calls them 'axioms.' He does not say that he assumes them to be true *provisionally*, and that the warrant for accepting them as actually true will be found in the astronomically-proved truth of the deductions. He lays them down just as mathematical axioms are laid down—posits them as truths to be accepted *à priori*, from which follow consequences which must therefore be accepted. And though the reviewer thinks this an untenable position, I am quite content to range myself with Newton in thinking it a tenable one—if, indeed, I may say so without undervaluing the reviewer's judgment."

To the sneer in the last sentence, and the remark that follows to the effect that the reviewer had evaded an issue "which it was inconvenient for him to meet," I shall reply by recommending Mr. Spencer to dogmatise either less elaborately or less rashly about the views of a philosopher like Sir I. Newton, whose works are so accessible and whose style is so clear, and at once pass on to call his attention to two passages in Newton's letters to Roger Cotes, who was at the time superintending the printing of the *Principia*.

In speaking of the special sense in which he used the word "hypothesis"—a sense which quite justified him in saying of himself "hypotheses non fingo"—Newton says:—

"In experimental philosophy it is not to be taken in so large a sense as to include the first *Principles or Axiomes which I call the laws of Motion. These Principles are deduced from phenomena and made general by Induction, which is the highest evidence that a Proposition can have in this Philosophy.*" (Letter lxxxi., edited by Edleston.)

And in the next letter he says:—

"On Saturday last I wrote to you representing that Experimental philosophy proceeds only upon Phenomena and deduces general Propositions from them only by Induction. And such is the proof of mutual attraction. And the arguments for y[e] impenetrability, mobility, and force of all bodies, and *for the laws of motion are no better.*"

I must confess to feeling a difficulty in reconciling the above extracts with the view that Newton posits the laws of motion "as truths to be accepted *à priori*."

THE AUTHOR OF THE ARTICLE IN THE BRITISH QUARTERLY REVIEW.

An Experiment on the Destructive Effect of Heat upon the Life of Bacteria and their Germs

I RECENTLY carried out an experiment which I shall not soon have the opportunity of repeating, and which I am consequently anxious to put on record. It is probably now familiar to those interested in the matter, that the experiments of Dr. Sanderson have established the fact that in an infusion of turnips and cheese prepared as directed by Dr. Bastian, heating to a temperature of 102 C. is sufficient to prevent the subsequent development of life (Bacteria) in the infusion even when the exposure to that temperature is only maintained for a few minutes. Boiling for five or ten minutes, according to Dr. Sanderson, is not sufficient to prevent the subsequent development of Bacteria, but according to the experiments of Dr. Pode and myself, boiling for ten minutes or a quarter of an hour *is* sufficient, provided that care has been taken to exclude visible lumps of cheese, and when the infusion is enclosed in a tube which tube is submerged in boiling water. Further, Dr. Sanderson has stated the following most important result, namely, that exposure to the boiling temperature (100° C.) was in all cases sufficient to prevent the subsequent development of Bacteria if it was carried on for so long as *one hour*.

This being the case, it occurred to me that since in all probability Bacteria and their germs, or spores, are killed by *through-heating* to a temperature a little below 70° C. (as established by various experiments in regard to Bacteria, but not in regard to possible germs, and admitted by both sides in the controversy as to their biogenetic or abiogenetic origin), it is desirable to recognise in our experiments the two distinct factors of this through-heating to any given temperature—namely, (1) the temperature to which the infusion to be heated is to be exposed; and (2) the length of time during which it is exposed to that temperature. If one of these variables—the time—be taken as a horizontal, and this line be divided into equal spaces representing periods of five minutes—whilst the perpendicular represents the range of temperature divided into degrees from 65° C. to 120° C—and if the results of observations with a given infusion indicating the time of exposure to a particular degree of temperature required in order to prevent the subsequent development of Bacteria be marked off on such a scheme, we should expect to obtain a series of points defining an asymptotic curve, the time required at the highest temperature being infinitely small, and at the lowest temperature infinitely great. This curve would vary in its character according to the properties of the infusion made use of. It was my intention to determine the principal points in this curve for Dr. Bastian's turnip and cheese infusion, but at present I have only made a tentative experiment at a low temperature. Using tubes of quarter-inch bore and three inches in length half filled with Dr. Bastian's infusion, and then submerged in water maintained at the desired temperature, I found that exposure for *six hours* to *a temperature of* 75° C. *was sufficient* to prevent the subsequent development of Bacteria. The same infusion enclosed in a similar tube and not heated at all, teemed with living Bacteria after four days; the same infusion boiled for ten minutes in an open tube remained barren. I submit this plan for a series of experiments to the readers of NATURE, without attaching much importance to the single but definite result which is above recorded.

I have not seen any reference in the pages of NATURE to the experiments which have been carried on in German laboratories in consequence of Prof. Huizinga's advocacy of Abiogenesis. Dr. Paul Samuelson, experimenting with Huizinga's infusions under the direction of Prof. Pflüger of Bonn, has obtained results which negative the inferences of Prof. Huizinga. Dr. Samuelson's paper appeared in Pflüger's *Archiv*, during the past year, and another experimenter (to whom I am unable to refer explicitly) has obtained equally definite results opposed to the speculations of Bastian and Huizinga.

Paris, Feb. 8 E. RAY LANKESTER

Animal Locomotion

I AM surprised to find that the Duke of Argyll prefers a charge of plagiarism against me in 1874 (NATURE, vol. ix. p. 381), said to have been committed by me in a lecture delivered at the Royal Institution of Great Britain in 1867. As his Grace was present at the lecture in question, and lodged no complaint in writing or otherwise, it appears to me that the charge, if not unfounded and out of place, is at least out of time. As I am not conscious of having perpetrated the plagiarism attributed to me, I wish to apprise your readers that the lecture referred to is published *in extenso* in the Proceedings of the Royal Institution of Great Britain, under date March 22, 1867, and may be consulted by all interested in the present discussion. That I had no wish to appropriate from his Grace, but was, on the contrary, desirous of giving him due credit for what he had done, will, I hope, be evident from the following quotation :—"In order to utilise the air as a means of transit, the body in motion, whether it moves in virtue of the life it possesses or because of a force superadded, must be heavier than it. If it were otherwise, if it were rescued from the operation of gravity on the one hand, and bereft of independent movement on the other, it must float about uncontrolled and uncontrollable, as happens in the ordinary gas balloon. The difference here insisted upon was, I have learned since writing the above, likewise pointed out by his Grace the Duke of Argyll, in his very able and eloquent article in *Good Words*, entitled the 'Reign of Law.' . . . This article, I am glad to find, has been reprinted in a separate form with numerous illustrations, and should be read by all interested in the subject of aëronautics." ("On the various Modes of Flight in Relation to Aëronautics ;" Proceedings Royal Institution of Great Britain, March 22, 1867.)

The only passage in the lecture bearing upon the point at issue *is opposed* to his Grace's explanation of the direction of the down stroke of the wing and in accordance with that originally given by me and defended by Mr. Wallace in NATURE, vol. ix. p. 301. *It cannot consequently be regarded as a plagiarism.* The Duke, it will be remembered, contends that the wing of the bird strikes *vertically downwards* during the down stroke. I, on the other hand, believe that the wing, during the down stroke, invariably strikes *downwards and forwards*. In this Mr. Wallace agrees with me. The passage in question runs as follows :—

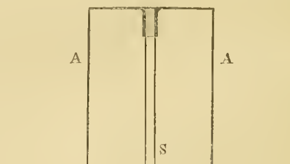
"All wings obtain this leverage by presenting oblique surfaces to the air, the degree of obliquity gradually increasing in a direction from behind *forwards and downwards* during extension, when the sudden or effective stroke is being given, and gradually decreasing in an opposite direction during fluxion or when the wing is being more slowly recovered preparatory to making a second stroke. The effective stroke in insects, and this holds true also of birds, is therefore delivered *downwards and forwards*, and not as the majority of writers believe, vertically, or even slightly backwards. This arises from the curious circumstance that birds, when flying, actually fall through the medium which elevates them, their course being indicated by the resultant of two forces, viz., that of gravity pulling vertically downwards, and that of the wing *acting at a given angle in an upward direction*. The wing of the bird acts after the manner of a boy's kite, the only difference being that the kite is *pulled forwards* upon the wind by the string and the hand, whereas in the bird the wing is *pushed forwards* on the wind by the weight of the body and the life residing in the pinion itself." (*Op. cit.*, March 22, 1867.) The Duke, it is true, compares the expanded motionless wings of a bird when sailing to a kite, while I, as stated, attribute a kite-action to the wings both when they rise and fall. The kite-action in the one instance is, however, not to be confounded with the kite-action in the other. That the wings invariably strike *downwards and forwards* during the down stroke, and *upwards and forwards* during the up stroke, and act as kites in either case, is a matter of observation, but still more of experiment. I have again and again witnessed the movement in the crow, cormorant, wild duck, and other birds, and repeated experiments with natural and artificial wings serve more and more to convince me that what I state is correct. But for the downward and forward and upward and forward curves made by the wings during the down and up strokes, progressive flight would be impossible. The curves in question, when the bird is advancing, unite to form *waved tracks* on either side of the body, thus representing the paths pursued by the vibrating wings in every form and variety of flight.

With regard to the poetical quotation introduced by me in my lecture and alluded to by his Grace, I venture to think that few will regard this as a case of plagiarism.

Edinburgh, March 23 J. BELL PETTIGREW

Electric Experiment

THE following striking experiment to show the rapidity of the influence of sulphuric acid in removing the invisible film of moisture that in ordinary circumstances adheres to the surface of glass and deprives it of its quality as an electric insulator, was recently shown to the Natural Philosophy class in the University of Glasgow by Sir William Thomson, and as it may be interesting to some of your readers, I send you an account of it. The apparatus used were a gold-leaf electroscope, and one of the ordinary table insulators long used in this University, of which the following is a description. A A is a hollow cylinder of brass, the lower part of which can be readily detached, replaced, and fixed in position by a bayonet-joint. The cylinder is supported at the top by the glass rod S, which passes through a circular opening in the bottom of the cylinder and is fixed to the sole plate C. In the lower part is placed a circular canal of lead containing a number of pieces of pumice stone *p p*, which for insulating purposes are moistened with a few drops of strong sulphuric acid. On the previous evening the pumice *pp* was moistened with a few drops of water, the cylinder closed and



left till morning. The experiment was then performed thus The gold leaves of the electroscope were connected with A A by a fine wire and a charge communicated ; the gold leaves at first repelled each other, but almost immediately collapsed. This was repeated once or twice, to show distinctly that there was no insulation.

The pumice containing water was then removed, and was replaced by other pieces moistened with sulphuric acid (in both cases the moistening was so little that the pumice had the appearance of being quite dry) and the vessel was closed. As the experiment was made towards the end of the lecture and time was pressing, a warm hand was placed on the side of the insulator to accelerate the drying process by creating connective currents in the air. Whether this hastened the effect or not sensibly it is impossible to say, but the insulation at once began to improve, and in less than five minutes it was shown to be perfect by the gold leaves remaining diverged to their full extent.

The University, Glasgow, March 21 D. M'FARLANE

Fertilisation of the Fumariaceæ

THE accompanying note has been given me by my friend Mr. J. Traherne Moggridge, and I should feel obliged if you would insert it in NATURE with the view of eliciting the communication both of other similar phenomena, and of some explanation of them.

ST. GEORGE MIVART

Mentone, March 18

Note on apparently useless Colouring in the Flowers of a Fumitory (*Fumaria capreolata var. pallidiflora, F. pallidiflora* Jord.)

I observe that in this plant at Mentone the flowers attain their brightest colouring after the ovaries are set, and when fertilisation is no longer necessary, or indeed possible. During the period previous to impregnation, the flowers are pale and nearly white, and the pedicels erect or horizontal; afterwards they become pink, or even crimson, and the pedicels are recurved, and the colour of the petals, which retain their form and position ntil the ovary has nearly attained its full size, intensifies with the lapse of time.

If the reverse had been the case there is little doubt that we should have regarded the bright colouring as specially adapted to attract insects, and as existing for that purpose, insects being, according to Prof. F. Hildebrand,* important agents in the fertilisation of fumitories; but here, as the brighter flowers are those which no longer need or are capable of profiting by the interference of insects, this explanation ceases to be possible.

This little fact, therefore, would seem to be one which might be classed with those which teach us that, side by side with the developments and modifications which are plainly beneficial to the organism of which they form a part, there are others, which, as far as we can see, are neither useful nor harmful to their possessor, though they may, and frequently do, supply features which especially attract our attention and admiration.

J. TRAHERNE MOGGRIDGE

* "Ueber die Bestäubungsvorrichtungen bei den Fumariaceen," in Pringsheim's "Jahrbücher," vol. vii. part 4, p. 423 (1870). Reviewed in "Bull. Soc. Bot. de France," xix. (1872), p. 145.

OCEAN CURRENTS

TWO papers which Mr. Croll has recently published "On the Physical Cause of Ocean Currents" (*Philosophical Magazine* for Feb. and Mar. 1874), bring the main question at issue between him and myself into very distinct view; and as the results of the *Challenger* Temperature-survey of the Atlantic, lately made public by the Admiralty, afford (as it seems to me) important data towards the settlement of this question I shall be glad to be allowed to point out what seem to me their chief bearings upon it.

The position taken by Mr. Croll is, that all the great movements of ocean-water, deep as well as superficial, depend on the action of winds upon its surface. And whilst freely admitting that Polar water finds its way along the floor of the great ocean-basins into the equatorial area, he affirms that this is merely the reflux of the current which has been driven into the Polar basins by the agency of winds.

On the other hand, it is fully recognised by myself, that the *current* movements of *surface*-water are, for the most part, produced by the agency of winds; but these movements, I contend, all belong to a *horizontal circulation*, *which tends to complete itself*,—a surface indraught being produced wherever a surface outflow is kept up, as we see in the horizontal circulations of the North and South Atlantic, the North and South Pacific, and the Indian Ocean, depicted in Mr. Croll's own map. But I maintain that the *deep* movements of ocean-water are the result of a *vertical circulation*, which is maintained by the continuance of a disturbed equilibrium between the Polar and equatorial columns, occasioned by the surface-action of Polar cold and equatorial heat.

As Mr. Croll is unable to understand why I should speak of Polar cold, rather than equatorial heat, as the *primum mobile* of this vertical circulation, and accuses me of an ignorance of the fundamental principles of physics in so regarding it, I may be allowed first briefly to explain myself; since others may experience the same difficulty, from some want of precision on my part in stating my case. The eminent physicists, however, with whom I have had the advantage of discussing this point, do *not* share Mr. Croll's objection, but hold my statement to be perfectly correct.

Heat applied to the *surface* of any body of *fresh* water, whether by solar radiation, or by the experimental application of a heated plate, will raise the temperature of the *surface-film*, without producing any downward convection. Limited downward convection, however, is occasioned in *salt* water by the sinking of the surface-films which are concentrated by evaporation; but this convection I found in my Mediterranean observations, which have been fully confirmed by those of the *Challenger* in the equatorial area, to be practically limited to the first fifty fathoms. Water in a long trough may thus be superficially heated (as I have experimentally ascertained), by the application of surface-heat to one-sixth of its length, until the temperature of its whole surface-film is raised to 100° or more; but the further application of surface-heat expends itself in vaporisation, and does not communicate itself in any sensible degree to the mass of water beneath, which, therefore, *can not be put in motion* by such application. On the other hand, the moment that *surface-cold* is applied, a downward convection is produced, as Mr. Croll may easily ascertain for himself if he will only try the experiment; and the continued application of such surface-cold to any one portion of the surface will maintain a constant movement through the entire mass of the liquid, until thermal equilibrium is restored by the cooling-down of the whole. But if the restoration of this thermal equilibrium be prevented by the application of heat to another part of the surface, the disturbance of equilibrium will be kept up, and a *vertica circulation* maintained, as long as these two opposing agencies are in operation. If Mr. Croll cannot see that this *must be* the case, I am not responsible for his failure to apprehend that which theory and experiment alike sanction.

I re-affirm, then, that *cold* applied to the *surface* has exactly the same motor power as *heat* applied at the *bottom*; and that its motor agency is more potent than that of heat applied at the surface, simply because the former is diffused by convection through the entire mass of the water, which it keeps on *cooling* and *moving*, whilst the latter is limited to the surface-film, and expends itself in producing evaporation.

Mr. Croll objects to this, that, if it were true, nearly the whole mass of oceanic water must have an almost Polar temperature. I accept this issue; and refer to the *Challenger* temperature-soundings, as justifying it. If he will look at the section taken across the equator, he will find that—*as I had predicted*—Polar water there lies within a very short distance from the surface. At less than 100 fathoms' depth, the temperature falls from 78° at the surface to 55°, and the isotherm of 40° is reached at about 320 fathoms. Below this lies a *stratum of more than* 2,000 *fathoms thickness*, whose temperature, ranging downwards from 40° to 32°·4, shows it to consist mainly of Polar water. And as, from the data supplied by the Mediterranean and Gulf of Suez temperature-soundings, a body of equatorial water secluded from all connection with the oceanic circulation might be expected to have the uniform (or isocheimal) temperature of 75° from 50 fathoms downwards, it is clear that the influence of Polar cold here extends itself upwards within 100 fathoms of the surface.

Again, Mr. Croll says that I have made no allowance for the *excess* of salinity in equatorial water, which, according to him, must counterbalance the increase of specific gravity produced in Polar water by the reduction of its temperature. Here, again, he is unfortunate

as regards his facts. He appears to have overlooked the observations proving the *lower* salinity of inter-tropical water, which I had cited as furnishing an additional indication that Polar water is constantly rising from the bottom towards the surface in the equatorial area. These observations have been most remarkably confirmed by those taken by the physicists of the *Challenger*. For, whilst in the extra-tropical area the sp. gr. of surface-water was in excess of that of bottom-water, in the equatorial area it was reduced to an almost precise correspondence with it, due allowance for temperature being of course made.

According to Mr. Croll's doctrine, the whole of that vast mass of water in the North Atlantic, averaging, say, 1,500 fathoms in thickness, and 3,600 miles in breadth, the temperature of which (from 40° downwards) as ascertained by the *Challenger* soundings, clearly shows it to be mainly derived from a Polar source, is nothing else than *the reflux of the Gulf Stream*. Now, even if we suppose that the whole of this stream, as it passes Sandy Hook, were to go on into the closed Arctic Basin, it would only force out an equivalent body of water. And as, on comparing the sectional areas of the two, I find that of the Gulf Stream to be about 1·900th that of the North Atlantic underflow; and as it is admitted that a large part of the Gulf Stream returns into the Mid-Atlantic circulation, only a branch of it going on to the north-east; the extreme improbability (may I not say impossibility?) that so vast a mass of water can be put in motion by what is by comparison such a mere rivulet—the north-east motion of which, as a distinct current, has not been traced eastward of 30° W. long.—seems still more obvious.

Lastly, the *Challenger* observations in the South Atlantic have proved exactly what I had anticipated, viz., that the bottom-temperature is lower, and that the Polar underflow lies much nearer the surface in this ocean than in the North Atlantic. Now this case appears to me to afford the *experimentum crucis* between Mr. Croll's doctrine and my own. For my prediction of this result was based on the fact, that, as there is here a perfectly open communication between the Polar and equatorial areas, the vertical circulation would take place more freely. On the other hand, according to Mr. Croll's doctrine, it would have been expected that there should be a far smaller reflux, or no reflux at all. For, though a portion of the equatorial current passes southwards when it meets the coast of South America, there is no ground whatever for believing that it ever goes near the Antarctic circle; and if it did find its way thither, there is no "closed basin" from which it can drive back a return current.

As it is usually considered in scientific inquiry that the verification of a prediction affords cogent evidence of the validity of the hypothesis on which it is based, I venture to submit that so far my case has been made good.

WILLIAM B. CARPENTER

THE DEATH OF DR. LIVINGSTONE

THE daily papers have obtained from the London office of the *New York Herald* the following telegram, containing details of the death of Dr. Livingstone, dated Suez, Sunday, March 29:—

"The *Malwa* arrived off Suez at eleven on Saturday night, having Mr. Arthur Laing and Jacob Wainwright on board, with the body of Livingstone. He had been ill with chronic dysentery for several months past. Although well supplied with stores and medicine, he seems to have had a presentiment that the attack would prove fatal. He rode a donkey, but was subsequently carried, and thus arrived at Muilala, beyond Lake Bemba, in Bisa country, when he said, 'Build me a hut to die in.' The hut was built by his followers, who first made him a bed. He suffered greatly, groaning night and day. On the third day he said, 'I am very cold; put more grass over the hut.' His followers did not speak or go near him. Kitumbo, Chief of Bisa, sent flour and beans, and behaved well to the party. On the fourth day Livingstone became insensible, and died about midnight. Majuahra, his servant, was present. His last entry in diary was on April 27. He spoke much and sadly of home and family. When first seized he told his followers he intended to change everything for ivory, to give to them, and to push on to Ujiji and Zanzibar, and try to reach England. On the day of his death the followers consulted what to do. The Nassick boys determined to preserve the remains. They were afraid to inform the Chief of Livingstone's death. The secretary removed the body to another hut, around which he built a high fence to ensure privacy. They opened the body and removed the internals, which were placed in a tin box and burned inside the fence under a large tree. Jacob Wainwright cut an inscription on the tree as follows:—'Dr. Livingstone died on May 4, 1873,' and superscribed the name of the head man Susa. The body was preserved in salt, and dried in the sun for twelve days. Kitumbo was then informed of the death, and beat drums and fired guns as a token of respect, and allowed the followers to remove the body, which was placed in a coffin formed of bark, then journeyed to Unyanyembe about six months, sending an advanced party with information addressed to Livingstone's son, which met Cameron. The latter sent back a bale of cloth and powder. The body arrived at Unyanyembe ten days after advanced party, and rested there a fortnight. Cameron, Murphy, and Dillon together there. Latter very ill, blind, and mind affected. Committed suicide at Kasakera; buried there. Here Livingstone's remains were put in another bark case, smaller, done up as a bale to deceive natives who objected to the passage of the corpse, which was thus carried to Zanzibar. Livingstone's clothing, papers, and instruments accompany the body. When ill Livingstone prayed much. At Muilala he said, 'I am going home.' Chumah remains at Zanzibar. Webb, American consul at Zanzibar, is on his way home, and has letters handed to him by Murphy from Livingstone for Stanley, which he will deliver personally only. Geographical news follows. After Stanley's departure the Doctor left Unyanyembe, rounded the south end of Lake Tanganyika, and travelled south of Lake Bemba, or Bangneoleo, crossed it south to north, then along east side, returning north through marshes to Muilala. All papers sealed. Address Secretary of State, in charge of Arthur Laing, a British merchant from Zanzibar. Murphy and Cameron remain behind."

These details are few but intensely touching. We believe that the Peninsular and Oriental Company's Bombay steamer *Malwa*, with Dr. Livingstone's body on board, is due on April 13 at Southampton. The body will be landed at that port and conveyed to London, by railway, for interment in Westminster Abbey; it is to be regretted that the faithful Chumah does not accompany his master's remains. It is impossible that Government will fail in doing what the whole civilised world takes for granted it will do—pay all possible honour to the remains of H. M. Consul, and of probably the greatest traveller that this or any other country ever produced.

REPORT OF PROF. PARKER'S HUNTERIAN LECTURES "ON THE STRUCTURE AND DEVELOPMENT OF THE VERTEBRATE SKULL"

THE new Hunterian Professor, Mr. W. Kitchen Parker, has just completed his course of eighteen lectures at the College of Surgeons, embodying in them the results of his researches on that most difficult problem, the deve-

lopment of the vertebrate skull. The plan pursued by Mr. Parker has been to describe first in their adult state, and afterwards in the various stages of their development, the skulls of certain prominent vertebrates which should serve as types for the other members of the group, and to deduce from the facts thus established the principles on which the cranium is constructed in the whole sub-kingdom. The types selected were the shark, skate, salmon, axolotl, frog, snake, fowl, and pig.

I.—*Morphological Elements of the Skull.* Nothing can be more hopeless than the attempt to unravel and explain the vertebrate skull by the study of adult forms only. The modification of face and brain-case, in the long line of creatures which begins with the lamprey and ends with man, are so endless that, until the study of embryology put the matter on a new and firm foundation, the best observers failed signally to produce a true "theory of the skull," the most elaborate attempt of the kind—the "vertebral theory" started by Goethe and Oken in Germany, and perfected by Prof. Owen in England—having resulted only in a convenient working hypothesis.

When, however, instead of starting with the highly differentiated skulls of adult animals, the embryos of these animals from their earliest conditions are made the subject of investigation, a new light is shed on the whole question. It is found that the skulls of all the vertebrata which have yet been thoroughly worked out, originate in, practically, a precisely similar manner; and even in some of the more advanced stages it would be hard to point out very essential differences between the skulls of a fish, a bird, or a mammal. Before entering upon the description of the skull of the shark, the first type to be gone into,* it will be advisable to consider the distinct elements of which the *primordial cranium* of any vertebrate animal is made up.

a. On either side of the anterior termination of the notochord, or primitive axis of the body (Fig. 1, Ch.), is developed a cartilaginous plate (I.M), which as a rule unites both above and below the notochord with its fellow of the opposite side. These plates taken together were termed by Rathke the *investing mass*: in the language of Prof. Huxley, they constitute the *parachordal elements* of the primordial skull or *chondro-cranium*.

b. In front of and below the investing mass, cartilaginous thickenings with intervening spaces are developed in the side walls of the body, enclosing, rib-like, the

Ch, Notochord; Vr^1, Vr^2, first and second vertebræ; I.M, investing mass; Au, auditory capsule; E, eye; Na, nasal capsule; Tr, trabecular; Mn, mandibular; Hy, hyoid; Br.1-5, branchial arches; Pl.Pt, pterygo-palatine process; M, mouth; Ty.Eu, tympano-Eustachian passage; Cl.1-5, branchial clefts; V^1, orbito-nasal; V^2, maxillary; V^3, mandibular; V^4, palatine division of the trigeminal nerve; VII^a, vidian; VII^p, hyomandibular divisions of portiodura; IX, glossopharyngeal; X, vagus.

pharyngeal cavity. These are the *visceral arches* (pleural elements, Huxley), the spaces between them the visceral clefts. The usual number of these bars is eight, although in certain exceptional cases they may be increased to nine (Hexanchus) or ten (Heptanchus). Taken from before backwards, the pleural arches are named as follows:—1. trabecular (Tr), 2. mandibular (Mn), 3. hyoid (Hy), 4-8. branchial (Br. 1—5), the clefts separating them being in like manner, the mouth (M), the tympano-Eustachian passage (Ty Eu) and the branchial clefts (Cl 1—5). At a very early period, the mandibular arch gives off a forward process, the palato-pterygoid arcade (Pl Pt) which in certain cases takes on the form of a distinct pleural element. In the branchiate vertebrata (Fishes and

Amphibia) all these arches with the single exception of the trabecular may bear functional gills, the presence of these organs being the chief physiological test of their serial homology.

Far more important, however, in the determination of these elements of the skull, are the morphological landmarks afforded by the cranial nerves, especially by the 5th, 7th, 9th, and 10th pairs. It is the constant habit of these nerves to fork above a visceral cleft, one of the branches thus formed supplying the posterior face of the arch in front of the cleft, the other the anterior face of the arch behind and (see Fig. 1). The orbito-nasal or ophthalmic (V^1) and the palatine (V^4) divisions of the trigeminal are the special trabecular nerves, the former passing over the optic nerve, the latter below it. The posterior primary subdivision of this nerve passes behind the mouth-cleft, and divides into two branches, both of which are distributed to the anterior (or in the altered position of the three foremost arches, outer) side of the mandibular arch; the mandibular, or inferior maxillary nerve (V^3) passing along the original direction of the arch, the superior maxillary (V^2) following the pterygo-palatine process. The seventh nerve, or portiodura, divides above the tympano-Eustachian passage, its anterior

* The development of the skull in the Marsipobranchii (Lamprey and Hag), the lowest group of craniate Vertebrata, has not yet been studied with sufficient accuracy to allow of the determination of its parts with any degree of certainty.

branch (VII[a]) going to the inner (posterior) side of the mandibular arch, and its posterior (VII[p]) division to the outer side of the hyoid. The glossopharyngeal (IX.), in like manner, is distributed to the inner side of the hyoid and the front face of the first branchial, the hinder face of which, as well as all the remaining branchial arches, is supplied by the great tenth nerve, or vagus (X).

By Rathke, to whom are due the first accurate observations on the development of the skull, the trabecular arches were looked upon as mere forward processes of the investing mass, and were called *trabeculæ cranii*, or "rafters of the skull." This misconception of their true nature arose from the fact that they very soon coalesce with the investing mass, and are only to be found distinct in extremely early stages.

c. Round the organs of smell and hearing cartilaginous investments are formed, known respectively as the nasal (Na) and auditory (Au) capsules. The latter become, at a very early period, united with the investing mass, while the nasal capsules come into close relations with the anterior or distal ends of the trabeculæ.* These are the *paraneural elements* of the primordial skull.

d. Certain cartilages may be developed in relation with and external to the visceral arches, called from this circumstance "extra-viscerals." Of this nature are the labial cartilages, which take so large a share in the formation of the skull of many cartilaginous fishes.

e. Lastly, the general membranous roof and walls of the brain-case may chondrify to a greater or less extent, but this chondrification is in nearly every case continuous with the trabeculæ and nasal capsules in front and below, and with the investing mass and auditory capsules behind.

Not only is the originally membranous cranium thus strengthened by deposits of cartilage, but osseous deposits may take place either in the primordial skull itself, or in the subcutaneous tissue surrounding it. The latter are called "investing-bones," or *parostoses;* the former may be of two kinds; when occurring as mere calcifications of the substance of the cartilage, they are known as *endostoses*, when having the structure of true bone, as *ectostoses*.

II.—*Skull of the Shark* (*Lesser Spotted Dog-fish*, Scyllium canicula).—The skull of the shark is one of the best examples of the chondro-cranium in its least altered state, being entirely uncomplicated by the development of investing bones, and covered simply by a close-set series of superficial calcifications.

The brain-case is much flattened both above and below. Seen from above, it is greatly excavated in its central portion by the orbits, but expanded in front by the rounded nasal capsules (Fig. 2, Na), and behind by the more or less quadrate auditory capsules (Au). The cartilaginous roof of the skull, or *tegmen cranii*, is interrupted by an oval membranous space, or "fontanelle," situated between the hinder boundaries of the nasal sacs, a position peculiar to the sharks. The upper surface of the otic capsules exhibits three well-marked elevations for the semi-circular canals, and just within that for the anterior canal, a small rounded aperture, the remains of the primitive involution of the integument from which the organ of hearing arose. An elevation on the hinder end of the posterior canal marks the position of the epiotic ossification so well developed in the osseous fish; the pterotic is also indicated by a large outstanding process (Pt O) which forms the postero-external angle of the skull, and the sphenotic (post-frontal of Cuvier) by the posterior portion of the supra-orbital ridge (S Or) when it coalesces with the auditory capsule (Sp O). The anterior extremity of this ridge forms in like manner the pre-frontal process. One very noteworthy point, observable both in an upper, under, or side view, is the presence between the nasal capsules of a short rod of cartilage (B Tr) representing the median basal portion, or keystone of the trabecular arch, and hence called the basi-trabecular.

Viewed from behind, the skull presents a large foramen magnum, bounded below and at the sides by the well-developed occipital condyles, between which is a slight elevation, showing the point where the notochord originally entered the investing mass. External to the occipital foramen, and marking the original boundary between the parachordal and otic elements of the skull is the foramen for the exit of the 9th and 10th nerves. The trigeminal foramen, which always points to the anterior limit of the otic region, forms a large aperture in the side wall of the brain-case (V), as also does the optic foramen (II).

The jaws are very loosely united to the other parts of the skull, and consist of an upper and a lower dentigerous arch, the former of which is connected with the skull by two bands of ligamentous fibres. The lower arch (Mck), which articulates with the posterior end of the upper, is the homologue of Meckel's cartilage, the rod which forms the foundation of the lower jaw in all vertebrata, but which as a rule, owing to the great development of investing bases, is reduced to a more slender style, or is even suppressed altogether. The posterior portion of the upper dentigerous arch (Qu) answers to the quadrate, a bone which in all Teleostei, as well as in Amphibia and Sauropsida, gives attachment to the mandible. The remainder of this "upper-jaw" represents the series of bones (pterygoid, meso-pterygoid, and palatine) which in the osseous fish connect the quadrate with the fore-part of the skull, the meta-pterygoid or proximal end of the mandibular arch being represented by the band of fibrous tissue (M Pt) which connects the quadrate with the auditory capsule.

Close behind the attachment of the meta-pterygoid ligament, a large phalangiform cartilage (H M) is articulated to the auditory capsule; this represents the hyomandibular of the osseous fish, the largest bone in the suspensory apparatus of the lower jaw, and the uppermost portion of the hyoid arch. Between this cartilage and the meta-pterygoid is a space (Sp), which in the recent state forms a communication between the cavity of the mouth and the exterior. This is called the spiracle, and answers to the tympano-Eustachian passage of the higher vertebrata. The distal portion of the hyoid arch consists of a large and strong cartilage, the cerato-hyal (C Hy), below which is a basal piece, common to both sides (shown in the figure by dotted lines), the basi-hyal. This is an extremely simple mode of segmentation of the hyoid arch, and approaches nearly to the primitive condition.

The cerato-hyal is connected with the mandible by a ligament—the mandibulo-hyoid ligament (mhl).

There are five branchial arches, all of which are split up into four segments, called, after the names originally given by Prof. Owen to the corresponding parts in the Teleostei, pharyngo- epi-, cerato-, and hypo-branchial. The inferior median piece, or basi-branchial (B Br), occurs only in the hinder part of the series.

The extra-viscerals are represented by the labial cartilages (l^1—l^5) and by the extra-branchials (Ex Br 1—5), between which and the branchial arches extend cartilaginous rods, acting as supports to the septa between the gill-pouches. The last arch, however, bears no gill and has no extra-branchial corresponding to it. The hyoid also is devoid of an extra-visceral, although it bears a series of greatly divided cartilages, which support the anterior wall of the first gill-sac; this arch, consequently, carries a half-gill. The branchia of the mandibular arch is represented by a vascular plexus (pseudo-branchia) on the anterior side of the spiracular opening.

* The Sclerotic, the fibrous (mammalia), or cartilaginous (Sauropsida and Ichthyopsida) capsule developed around the organ of sight (E) never really forms part of the skull, although in the sharks and rays, and some osseous fish, it is articulated with the side walls of the brain case by a cartilaginous pedicle. The form of the skull is, however, greatly governed by the presence of these optic capsules.

NOTES

AN International Horticultural Show is to be held at Florence in May, from the 11th to the 25th. The *Société Royale Toscane d'Horticulture* offers 100 medals of gold, 221 of silver, and 131 of bronze, and five grand *prix d'honneur* are offered respectively by the King of Italy, the Minister of Agriculture and Commerce, the province of Florence, the town of Florence, and the lady patronesses. Prince Demidoff and Prof. Parlatore have also placed gold medals for special classes, at the disposal of the committee. Coincidently with the Show the International Botanical Congress will be held at Florence under the presidency of Prof. Parlatore. The programme of subjects for discussion includes questions on the nature and functions of hairs on plants, on cell circulation, on the latex, on the automic movement of the leaves of plants, on the causes which determine the direction of the root in the germination of a seed, on the causes which influence the direction of the growth of branches, especially of weeping trees, on the analysis of the organs of reproduction between cryptogams and phanerogams, as well as many other subjects more widely known, and subjects of debate such as the origin of *Bacteria*, the determination of fossil plants by their leaves, the distinction between *species*, *race*, and *variety*, and the origin of insular and alpine floras. The President and Secretaries of the *Société Royale Toscane d'Horticulture* announce their readiness to communicate with any botanists who wish for further information with a view to attending the Congress. The official language of the Congress will be Italian, but papers may be communicated and discussions conducted in any language. Representatives to the Congress have been appointed from the various countries of Europe, and from Egypt, Australia, Mexico, Brazil, &c. Among the names of those who are expected are announced the following English botanists:—Messrs. Hooker, Trimen, Ball, Hiern, Hogg, Maw, Murray, Allmann, and Binney. As a measure of precaution against the introduction of the *Phylloxera*, the importation of vines and of other fruit-trees into Italy has been rigorously prohibited since October 31 last.

THE Syndics of the Cambridge Botanic garden in their annual report state that the Curator has nearly completed the re-arrangement of the herbaceous plants, and it is hoped the laborious task will be finished in the ensuing year. The plant houses are in a good state of repair, but over-crowded. The Professor and Curator are unable to see in what manner the number of plants kept in them can be materially reduced without injuring the efficiency of the garden. Several of the finest and most valuable specimen plants now threaten to grow through the roof of the houses. The Syndics acknowledge some donations of foreign seeds and plants, but they are under the necessity of discouraging gifts of seeds of plants belonging to warmer regions, because of the want of room for their proper cultivation.

WE are very glad to hear that negotiations are pending for the transfer of the valuable Museum of Natural History, which was formerly in the possession of the East India Company, from the India House, where it has been for some time stored, to South Kensington, where it will at last be available for reference and study. This desirable transfer we strongly recommended in an article which appeared about a year ago (NATURE, vol. vii. p. 457).

A PURSE of 540 guineas has recently been presented by members of the British Association and other friends to Mr. W. Pengelly, F.R.S., F.G.S., as a testimony to the high value of his labours in conducting the exploration of Kent's Cavern, Torquay, and of his other services to science. After the presentation it appeared that many of Mr. Pengelly's friends and advisers had been left in ignorance of what was proposed. To enable all such persons to join in this mark of appreciation the hon. sec. to the testimonial fund, Mr. J. E. Lee, F.G.S., Villa Syracusa, Torquay, is prepared still to receive subscriptions up to the 17th of April.

A GERMAN Natural History and Anthropological Society for Eastern Asia has now existed for a twelvemonth, having been established on March 22, 1873. The headquarters is at Tokio, and the Society consists of fifty-two members, twenty-three being resident at Yokohama, twenty at Tokio, seven in Hiogo, and two at Singapore. Herr von Brandt, the Minister for the German Empire in Japan, is its president. The Society has already published a volume of "Proceedings," containing several interesting and important papers on the subjects for the cultivation of which the Society was founded, especially on the ancient customs and history of Japan.

A MONUMENT to Antonio Bertolini, author of "Flora Italica," has been inaugurated at Bologna.

DR. ASCHERSON, of Berlin, has gone to Egypt as a member of a commission of exploration. Prof. Planchon, of Montpellier, has been sent by the French Government to the United States to inquire into the new vine disease caused by the *Pemphigus vitifolia*. Other botanists at present occupied with foreign exploration are, Sig. Pichler in the east, and Messrs. Lorentz and Hieronymus.

THE chairs of Botany at the Universities of Genoa and of Modena were announced vacant at the end of January.

THE new edition of Pritzel's "Thesaurus" will be edited by Prof. Jessen.

PROF. STEFANO DE' ROSSI has just started in Rome a *Bulletino del Vulcani*. The learned geologist has undertaken to chronicle and to comment upon all the volcanic phenomena which are observed in Italy and the surrounding islands. Two parts of the periodical have been published, giving details of every commotion felt during 1873. The ground was in such activity that Prof. Stefano de' Rossi has been able to report more than three hundred separate phenomena. The mean number of seismic commotions in the whole Peninsula is almost *one daily*.

AN aëronautical experiment of great importance took place on March 22. The balloon "Etoile Polaire" was sent up with two aëronauts, M. Sivel and Croce-Spinelli, to test if the respiration of an air rich in oxygen would enable observers to reach a high level without being suffocated by the rarity of the surrounding medium. The experiment was suggested by M. W. de Fonvielle in his "Science en Ballon," and an apparatus was constructed by M. Paul Bert, Professor at the Sorbonne, and a Member of the National Assembly. The "Etoile Polaire" started at 11.40 A.M. from the La Villette gasworks, and at 12.4 P.M. had reached 5,000 metres. The temperature, which was + 13° C. on the ground, had sunk to − 10° C. M. Croce-Spinelli was almost suffocated, but by using the oxygenised-air respirator he recovered. His pulse, which was beating 86 on the ground, was beating 140, and with the respirator 120 only. These experiments were conducted from 12.4 to 1.30 P.M., when the balloon had reached 7,400 metres, where the thermometer sank to − 24°. No observation was taken during the descent, which took place at 2.12 P.M. at Bar-sur-Seine, 120 miles from Paris. On landing, the temperature was + 17°. M. Croce-Spinelli had with him a little hand spectroscope supplied by M. Janssen. He states that all the aqueous lines belonging to the vapour had disappeared, and that the solar rays *D* and *F* were growing very dark. When not using the respirator the sky seemed quite dark, but the blue colour was restored when respiring oxygenised air. The measurement of the balloon was 2,800 cubic metres. It was elevated with 1,650 metres of lighting

gas, carrying with it 380 ballast, of which no more than 40 were left for descending from 7,400 metres. The altitude is higher than any French aëronaut has reached up to the present time, but Mr. Glaisher, without the help of any oxygenised air, navigated the atmosphere on several occasions to that distance from the sea-level—as on August 28, 1862, April 18, 1863, June 26, 1863, &c. He had no feeling of suffocation except when he reached 10,000 metres on September 5, 1862. It is to be supposed that with proper care and with persons properly trained and selected, the method, although efficacious, is not required except at higher level or for the purpose of increasing the comforts of aërial travellers. It is very probable that it is useless to keep several mixtures and that pure oxygen is better as being more efficacious and less bulky.

THIS year's International Exhibition at South Kensington opens next Monday.

AT the annual general meeting of the Royal College of Physicians of London, held on March 30, Sir George Burrows, F.R.S., was re-elected President of the College.

ASTRONOMERS will be interested to learn that among the numerous able men whom the President of the republic of Ecuador has gathered to that city in order to develop the University of Quito, there has appeared one, Father Menten, whose interest in astronomy has been such as promises to settle the long-mooted question as to an observatory in that city. Menten has now returned to Quito laden with a portion of the instrumental outfit that he was ordered to secure at Munich. Among the apparatus is a six-inch meridian circle. Father Menten was for some time a pupil of the eminent Argelander.

THE Royal Academy of Belgium has announced the following subject for its prize essay for 1875:—The relation of heat to the development of phanerogamic vegetation, especially with respect to periodic phenomena, and the value of the dynamic influence of solar heat on the evolution of plants.

IT has been proposed to hold a fungus show in Scotland; a preliminary meeting is to be held in Marischal College, Aberdeen, on April 14.

MR. J. C. MELLIS, late Commissioner of Crown Property at St. Helena, announces as in the press a work on the geology, fauna, flora, and meteorology of St. Helena. Separated so far as the island is from any mainland, and showing no trace of any former connection with a continent, there are many questions of interest as to the origin of its flora and fauna. This work is stated to be based on Mr. Mellis's own observations, and promises to be of great value.

MR. WATSON has brought to England a series of paintings by a Japanese artist illustrating some of the customs of the Ainos, who inhabit the island of Yezo, or Sesso as it is sometimes spelt, north of Niphon. Not much is known of the Ainos, but they are regarded as the aborigines of Yezo, who have been driven inland by the fringe of Japanese settlements all round the coast. The first of the series is said to represent the traditional origin of the race. A woman is in a cave weeping, and a dog is carrying to her a red flower, apparently a rose. It does not, however, appear to be known what this symbolises. A coloured drawing of a male Aino executed with great care and regard to detail, shows bows and arrows of native make and a sword of Japanese manufacture. A cord is worn round the head to help to form a support for a weight, as they never carry burdens on their backs. The portrait of a female shows the broad tattooing round the upper and lower lip and on the arms, as the sign of marriage. Both the male and female wear earrings, which is a contrast to the Japanese, who never wear personal ornaments. The woman is playing on a kind of guitar with five strings. In the views of the interior of the dwellings all cooking utensils have their Japanese names written against them by the artist, so that their use may be known though their shape is not familiar. Some of the series illustrate whale harpooning, which is done with a two-pronged harpoon, and many are devoted to the festival of the bear. After killing a bear they appear to sit round it in state solemnity, as if worshipping it and offering it food and drink. Dresses of many colours are worn, and the bear is decorated. Their commerce is represented as the collecting of seaweed, drying it, packing it in bundles and selling these by weight to Japanese. The drawings of the articles used for food, laminaria, crabs, holothuria, cuttle-fish, &c., are drawn with great detail and delicacy of colouring.

THE first volume of "Repertorium annuum Literaturæ Botanicæ Periodicæ," has appeared, published at Harlem under the editorship of Van Bemmalen. It professes to give an account, for the year, of all botanical papers read in full or in abstract before Societies, and also to notice memoirs and communications to Societies.

DR. L. JUST, Professor of Agricultural Chemistry in the Polytechnic School at Carlsruhe, has just published, with the co-operation of several distinguished men of science, an Annual of Botany, intended to form a complete record of all botanical works published during the year.

THE Bureau des Longitudes is no longer connected with the National Observatory of Paris. It is to have its own budget, library, and a public building will be arranged for its private use. The most influential member and president is M. Faye, who is making a public appeal to French astronomers asking them to devote themselves to the spectroscopic observations of the sun.

MR. W. S. CLARK, president of the Massachusetts Agricultural College, publishes a lecture On the Circulation of Sap in Plants, containing a great amount of information as to our knowledge of the subject, and a number of tables and diagrams to illustrate the maximum and minimum pressures of the sap in different trees. Mr. Clark maintains, in opposition to some recent statements, that there is a flow of crude sap upwards in the wood, and a flow of organisable material essential to the life of the plant proceeding from the leaf to the root through the bark and cambium layer, from which the growth of the season is formed.

THE annual *réunion* of the Sociétés Savantes des Départements of France, will take place at the Sorbonne from April 8 to 11.

ONCE every year French astronomers hold a general meeting at the office of the Minister for Public Instruction. It will take place this year in the beginning of April.

FRENCH officers belonging to the general staff are regularly attending the observatory to be trained in astronomy. A special building has been constructed for their use by M. Leverrier.

DR. HYRTL, the eminent Professor of Anatomy in the University of Vienna, delivered his final lecture on March 16, and took leave of his class. In the afternoon he met an assemblage of more than three thousand pupils and friends, who presented him with addresses and other expressions of esteem, which were feelingly acknowledged by him.

THE additions to the Zoological Society's Gardens during the past week include two Laughing Kingfishers (*Dacelo gigantea*) from Australia, presented by Mr. J. Hayward; a White-necked Crow (*Corvus scapulatus*) from the Gold Coast, West Africa, presented by Capt. E. Whitehead, 42nd Highlanders; an Eland (*Oreas canna*), born in the Gardens; two Yellow-headed Conures (*Conurus jendaya*) from south-east Brazil, purchased.

CELESTIAL CHEMISTRY*

II.

WE have now gone through as briefly as I can manage to do it, the principal points in chemistry and the principal points in spectrum analysis with which we have to deal when we are dealing with the chemical substances of our own planet. You see the point of inquiry is the chemical and spectroscopic study of the differences between atoms and molecules. We have now to apply these two lines of thought to a consideration of what I have called Celestial Chemistry.

In the first place, how is the study of Celestial Chemistry carried on? To answer this question I will give you an idea of the way in which the spectroscope is added to the telescope. We, of course, require a spectroscope in order to bring into play refraction or diffraction, and we equally, of course, require a telescope in order to collect the light which comes to us from the various light sources which are to be found in the sky. You now see a photograph of what is technically called the eye-piece end of the most perfect and most powerful telescope in the world, which I am proud to say is in England. It is the telescope belonging to Mr. Newall of Gateshead. We see the principal telescope and the various finders, which enable the observer to find the most delicate object which shines in the sky.

You will get an idea of the enormous quantity of light collected by this instrument, when I tell you that the diameter of the pupil of the eye is less than a quarter of an inch, and that the diameter of the object-glass of this telescope is 25 inches, and that the quantity of light utilised depends upon the squares of the diameters. Of course, when we have to deal with feeble celestial objects lying at an immense distance from us, and which give but little light, it would be absolutely impossible to use the prism with any effect unless in the first instance we thus collected a large amount of light to work with.

Now then, having our spectroscope attached to our telescope in the way indicated, to what must we turn our attention? You will see in a moment that it is useless to consider such a body as the moon. I say useless, of course bearing in mind that we are here dealing with chemical considerations, because the light which we get from the moon is simply sunshine second hand, and the moon has no atmosphere. The same remark applies to a certain extent when we deal with the planets, because they also, as you know, are lit up like the moon by the sun, but they have atmospheres, and much is to be learned from them in this way. What we have to do in the main to get a just general outline, in order to study this Celestial Chemistry is, to confine our attention to those bodies which shine by their own light. And if you think the matter over for a minute you will see that there are two distinct classes of such bodies. In the first place there are the *Nebulæ*, and *Comets*, and *Meteors*, which shine by their own light. And again, there are the *sun* and the *fixed stars*, which shine also by their own light; but with this important difference, that while we get the initial light radiated by a nebula, a comet, or meteor, the light which we get from a star is not the initial light, but a difference light; a great deal of the light radiated having been stopped by the atmosphere of the star. So that in the case of a sun, by which of course I mean a star—our sun being merely the star which is nearest to us—although it shines by its own light, we get a difference light while we get what we may call the total light from the first class.

And here let me add that i is the chemical composition of the atmosphere of the star which thus stops the light which we can study. If the stars had no atmospheres there could be no star chemistry, because their spectra would be continuous, and in that case neither qualitative nor quantitative spectrum analysis would be possible.

We deal then with radiation in objects of the first class and with absorption in objects of the second class.

Let us commence our study of those objects which shine by their own light by the study of the comets and the meteors. It is unfortunate that since the more general use of the spectroscope, no large comet has made its appearance, but still some small ones have been observed.

There is a spectrum which in the main is common to a great many of the compounds of carbon; and here I may parenthetically remark that carbon is, of the sixty-three elements to which I have referred, the only element which with the electric power that we can employ in the arc presents us with the distinct appearance of a compound spectrum. Side by side with this generic spectrum of the compounds of carbon I will show you the spectrum of the head of a comet which was observed some years ago; and I may add that several other comets have been observed since, with the indication that their spectra are to a very large extent, if not absolutely, the same; so that we may

FIG. 1.—Head and Envelopes of a Comet.

say there is a probability that, in the case of some of the comets at all events, we are dealing with a class of bodies in which a compound of carbon is concerned, or if not that, that the molecules of the comet resemble somewhat those of the chemical substances which give us such spectra.

Closely connected with comets by the recent hypothesis of

1 2 3 4

FIG. 2.—1, Spectrum of Brorsen's comet; 2, Spectrum of Winnecke's comet; 3, Spectrum of carbon in olefiant gas; 4, Spectrum of carbon in olive oil. (Huggins.)

Schiaparelli, are meteors, and falling-stars. So far as I know at present, in the case of falling stars the cometary spectrum has not been seen, but it has been noticed in several shooting-stars that the vapour of sodium is present, indicated by the double bright line in the yellow part of the spectrum. Now the meteorites are large meteors which have fallen to the

* Revised from short-hand notes of a Lecture delivered at the Quebec Institute, on Tuesday, December 16, 1873. Continued from p. 414.

earth, and this being so, we can chemically examine them as easily as substances which have consolidated here. These bodies may be roughly divided into iron meteorites and stone meteorites, and roughly again into meteorites which contain elementary metallic molecules, and others which contain compound molecules, that is, mixtures of metals with the metalloids.

The observations of the spectra of nebulæ we owe mainly to Mr. Huggins, a distinguished English observer, who has given very much attention to this branch of inquiry. One thing we know for certain about the nebulæ from these observations is this: we are dealing either with gases alone or with solids banging about in gases, and one of the bright lines which we observe tells us that we are dealing with hydrogen gas; so that the same method of inquiry which, applied to comets, tells us that probably in some cases we are dealing with a compound of carbon, tells us that we are chiefly dealing, in the case of nebulæ, not with a compound of carbon or with a compound of anything, but with a true element—hydrogen.

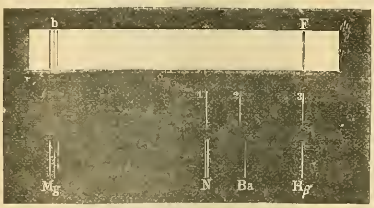

FIG. 3.—Spectrum of the nebulæ.—1, 2, 3, lines observed. Above, the solar spectrum is shown from *b* to F; below, the bright lines of magnesium, nitrogen, barium, and hydrogen, in the corresponding part of the spectrum.

That, you see, is a very great step; and a very few years ago it would have been considered presumptuous almost to think that man could ever tell what substances were building up the nebulæ which lie at such infinitely remote distances from us.

So much then for comets and meteors and nebulæ. These exhaust the bodies in space which shine by their own light, the light not being subsequently absorbed by an atmosphere through which it passes; we will now therefore pass to the class of Stars.

With regard to stars, I have a diagram to bring before you, which summarises in a convenient way a good deal of the work which has been very carefully done by Father Secchi of Rome. I shall have to refer to several other diagrams afterwards; but this, I think, is the best one to place before you in the first instance.

The spectra in the diagram are the spectra of various stars. You will at once see that there is a difference between those spectra, and you will see that there is a double difference between some of them. In the first place, you have an extreme simplicity in some cases and complication in the others. But you see, also, that the question of simplicity and complication is not the only question, that is a question merely of degree; but there is a difference in kind. For instance, you will at once acknowledge a difference in kind between the spectrum of α Herculis and Sirius.

FIG. 4.—Ring nebula in Lyra, with its spectrum.

The diagram of the former, although it has been made in no laboratory, and although it deals with no metalloids or no compounds which have been got upon the earth, is as good a diagram as I can put before you to explain what I mean by the channelled structure of the spectrum of the metalloids as opposed to the line spectrum of the metals.

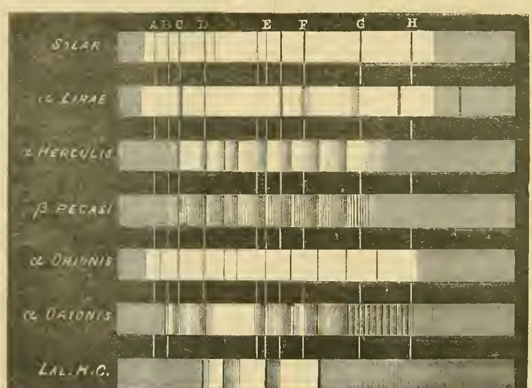

FIG. 5.—Various Stellar Spectra (Secchi).

Bearing in mind the great simplicity of the spectra of stars like α Lyræ and Sirius, and the greater complexity of the spectral lines in a star like the sun; bearing in mind, also, the difference in kind between the spectra that I have referred to, we can divide all the stars which shine in the heavens which we have already observed, into three classes. This has been done by Rutherfurd and Secchi.

Let me strengthen what I have to say by showing you rather more elaborate drawings of three stars belonging to these different classes. You will now see the importance of the considerations which I have brought before you regarding the spectra of the metals and the metalloids. There is the channelled space spectrum of the star α Herculis; there is the banded spectrum of the star α Orionis; and there is the equally banded spectrum of a star in the constellation of the Scorpion. In all these cases you will see we are dealing, not with the first class in which we have simple spectra, but with the second and third classes.

Now let me contrast on another diagram the spectra of two stars, one in the first class and the other in the second. Let us contrast the spectrum of Sirius with the spectrum of the star in Orion, to which I have already referred. In the spectrum of

Sirius observe—for this is a very important point—the extreme thickness of the lines, which are the lines due to hydrogen, and contrast the thickness of these lines and the simplicity of the spectrum with the thinness and great number of the lines in the star in Orion, and the complexity of its spectrum ; and remembering that both these maps are on the same scale, let me point out that all the lines which are so thick and so obvious in the spectrum of Sirius, are altogether wanting in the spectrum of the star in Orion.

I hope I have convinced you, by the sight of these diagrams, that supposing the observations on which they are based to be true, we have in the stars which shine three perfectly different kinds of absorption of light going on in the atmospheres of those stars. We have an absorption which we may call a simple absorption, seeing that the lines are few in number ; we have an absorption of the same kind, but different in degree, which we may call complicated, seeing that the lines are still lines, but that they are very much increased in number. And, again, in the third class we have an absorption of a different kind altogether ; instead of having an absorption of lines we have an absorption of bands. This I shall venture to call a metalloidal absorption.

Of course if we were merely limited to the spectrum of these distant stars, in spite of the enormous skill and care which Mr. Huggins and Father Secchi have brought to bear upon this inquiry, we probably should never go very much further; but you know that the sun is, after all, our sun, merely for the reason that it is the nearest star ; and therefore it is clear to you that if we observe the sun with anything like the attention that it deserves, bearing in mind its comparative nearness to us, we ought to be able to get out of the sun a great number of facts which will help us the better to understand the various appearances in the different stars.

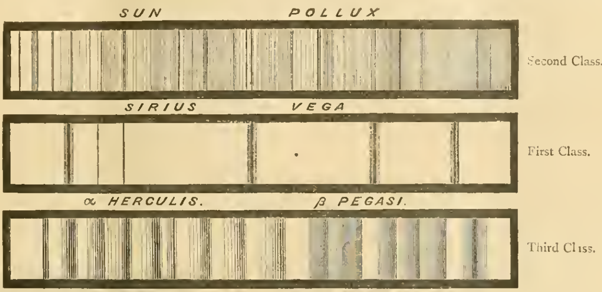

FIG. 6.—The Three Classes of Stars (Secchi).

I need not say to you that a great deal of trouble has been taken to understand the sun, to study its physical and even its chemical constitution ; and if you will allow me, I will put before you two or three considerations having reference to the sun, which have a bearing of considerable importance upon Celestial Chemistry.

In the first place, let me call your attention to the sun as we see it ordinarily. We see that on the sun there are spots, and that on the limb there is a dimming ; both the dimming of the limb and of the spots being due to the absorption of the sun's atmosphere which is at work, as I have already told you in the case of the stars, and which separates the stars as a class from the comets, meteors, and the nebulæ.

Next consider the sun as it is seen in an eclipse. Some of you may be surprised to learn that the sun, as we see it every day, is not by any means the whole sun, but only, so to speak, the kernel of an enormous mass of vapour extending for thousands and tens of thousands of miles around the visible sun.

Now in an eclipse, when all the sun ordinarily visible is hidden, we get indications of a very bright something extending to some little distance above the visible sun. On this point I may specially call attention to a photograph taken in the eclipse of 1870, at Syracuse, in which, outside the dark moon which is covering the sun, and therefore outside the sun, a mass of light which we know to be due to vapours surrounding the sun is indicated.

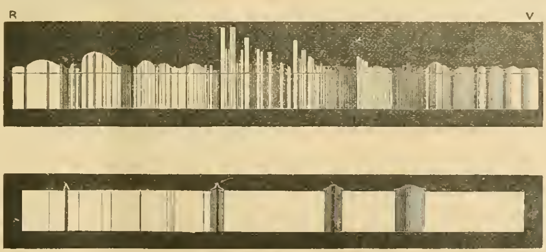

FIG. 7.—Spectra of α Orionis and Sirius (Secchi). In the spectrum of α Orionis the brightness of the spectrum is represented by the height.

In a photograph taken in India in the year 1871, under somewhat different conditions, we were fortunate enough to record a great deal more of the sun's surroundings. In this, surrounding the dark moon we have an immense mass of something not very bright extending to a very considerable distance indeed above the visible sun.

Now, by studying these phenomena in the case of the sun, of course we are studying similar things in the case of every star ; and what do we find ? We find, in the case of the sun, that surrounding the visible sun there extends to a very considerable distance an atmosphere of an element that we have not here, and which is probably lighter than hydrogen. Immersed in this, and therefore extending to a smaller distance from the sun, is another envelope, which has been called the chromosphere, consisting, in the main, of hydrogen. The brightest part of this lies pretty close to the sun. This region is excessively bright—so bright, that by a certain method it can be seen without any eclipse whatever. Immersed in this hydrogen and

therefore still nearer the sun there is an enormous quantity of vapours of the different elements existing in the sun, in what we may term a reversing layer, and it is to the absorption of the elements in this layer that the absorption of the sunlight, and therefore, so to speak, the creation of the spectrum of the sun, is in the main due.

I will now direct your attention to two photographs of the solar spectrum, and reminding you that the complexity of a spectrum depends upon the number of elements, and upon the pressure at which the vapours of those elements exist in the atmosphere of any star, you will gather from these photographs a pretty good idea of the extreme complexity of the sun's reversing layer to which I have referred.

In a photograph of any part of the sun's spectrum each of the lines of course has its story to tell, not only so far as the substance which is at work doing that particular part of the absorption is concerned, but also even so far as the quantity of that substance is concerned; because not only will a certain substance absorb particular waves of light, but it will absorb many waves, or few, or none at all, according to the quantity of that particular substance in the envelope surrounding the sun. Now there is a great deal of calcium in the sun, and therefore the absorption lines of the calcium are very thick, the absorption lines of the other metals which do not exist in such great quantities in the sun being very much thinner.

Having brought before you these various points connected mainly with the sun, so far as its physical constitution goes, let us consider what is the chemical constitution of the sun.

I have already told you that surrounding the sun is an envelope composed in the main of hydrogen, and of a new element, and that nearer to the sun is a region of vapours of great complexity, containing at least one new element. This region contains, besides hydrogen, and dealing with known elements, magnesium, sodium, titanium, calcium, nickel, chromium, iron, manganese, aluminum, copper, zinc, barium, cobalt, and so on, and latterly we have had reason to suppose that some six or seven new elements must be added to the list—potassium, lead, cerium, uranium, strontium, and cadmium. Further, if instead of the new "atomic weights" of the elements we take the old "combining weight" we find that the arrangement of these layers round the sun follows the vapour densities of the various substances either absolutely or very closely.

This then is the verdict of the prism with regard to the chemical constitution of the sun, the nearest star that we can get at; and I think you will acknowledge that if the prism had done nothing else it would have done good work. But I think it has done very much more, because it has enabled us not only to chronicle those things as existing in the sun, but in connection with the other facts which I have already brought before you it has enabled us to place the sun in its proper position amongst the stars. For instance, I have already called your attention to the first, second, and third classes of stars. Is the sun in the first, the second, or the third class? Does its spectrum contain few or many lines? or are there channelled spaces or bands? Its spectrum is not excessively simple; there are no channelled spaces or bands; and therefore the sun is to be placed in the second class of stars. Can we then go beyond this chronicle of facts, which I am afraid some of you may have considered rather dry?

You know that what a scientific man has to do in any research is not merely to add fact to fact, and to go blindly looking after facts irrespective of order. What he has to do after he has accumulated a certain number of facts is, to try whether it is possible to arrange them in order. If you wish to get a law out of any accumulation of facts in physics, in chemistry, or astronomy, you must first get your facts into order or you will never do it. Is there any possible order into which we can group these various facts to which I have referred? I venture to think there is.

Call to mind the three classes of stars. Is there any other physical quality tacked on to those differences? Yes. The stars with the simplest spectra are on the whole the brightest stars in the heavens; and the channelled spaced stars are on the whole the dimmest stars in the heavens. Of about 500 stars which have been already observed, over 300 are of the complicated second order or type. There are a great many bright stars of the first order, but an extremely small number, only, I think, about 27 of the third order with the channelled space spectrum. Now, if this be true, and if it be fair to assume that the star which is the brightest is on the whole the hottest, and I think it is fair to say so, if you take all other things as equal, then you come to a generalisation of this kind, that the brightest and hottest stars in the heavens have the simplest spectra, and the dimmest, reddest, coldest stars have a spectrum entirely different. If this be so, can we connect these facts? I think so. Grant these facts (and the future alone will show whether they are facts), and the thing is clear. We may group them all together by supposing that in the stars of the first and second classes there are dissociating forces at work which, from considerations which I have not time to bring before you now, we can imagine to be infinitely higher, or at least considerably higher, than any dissociating force that we can get here even with the electric spark. If you imagine in these stars an atom-severing force greater than we can obtain here, you can at once group in a working hypothesis all the facts which I have brought before you, and in a simple way; and let me add that simplicity in Science is a very great evidence of truth.

If you assume that at the highest possible temperature—here I use the word temperature for want of a better—of a star you have work done in continuation of the work done in terrestrial furnaces, that is to say, if instead of having 63 elements which we have here with our furnaces, there is a much smaller number, taking into consideration the increase of temperature, you will see at once that the brightest and hottest star in the heavens should have the simplest spectrum, because there you have the fewest elements, and that the coldest, reddest, dimmest star should have a spectrum indicating metalloids and compounds because you have there a low temperature, at which the metals do not exist except in combination. And if you think this matter over you will see that this suggestion of a higher temperature giving us a simpler condition of what we with our paltry temperatures call chemical elements, instead of making

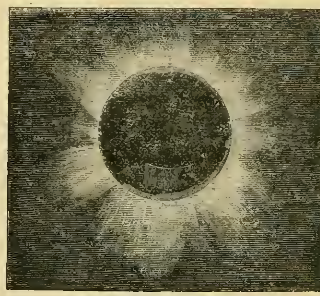

FIG. 8.—The Corona (Indian Eclipse, 1871).

these stellar spectra complicated, difficult to recollect and to understand, puts them all in one line easily to be grasped, and a line which I venture to think is somewhat coincident with the probabilities of the case.

Does the work stop there? Has it nothing to say to comets and meteorites? Here again it has a question to ask. The beautiful hypothesis of Schiaparelli, which is accepted by all astronomers, has made it perfectly clear that a comet is nothing more than one of an infinite number of meteors or meteorites, or whatever you like to call them, travelling in cometary orbits round the sun, and to which the showers of shooting stars are due. We know that there is a comet connected with that particular meteor swarm which gives us the November meteors, and we know that there is another comet connected with that particular meteor swarm which gives us the August meteors; and we assume that in all probability there are millions, or any enormous number that you like, of meteors, or meteorites, or shooting stars peopling a part or the whole length of that concrete orbit so to speak.

How is it then that there is only one comet amongst all that infinite number of potential meteors or meteorites? Here again I am sure that the future will enable the prism to throw an immense light, and we already have a glimmering. If, for instance, you assume that out of a star of the second class, in the reversing layer of which there are no metalloids, portions of the atmosphere are, by forces which we know to be at work, thrown bodily from the sphere of the star's attraction into space, those vapours on being cooled would give us very much the same kind of chemical composition that we get in the well-known masses called iron

meteorites, composed principally of iron and nickel. While on the other hand, in the case of stars of the third class, in which it seems excessively probable that we have both metalloids and compounds, and very little pure metal, that is to say, metal not in combination, in the reversing layer, we have also the large class of silicate meteorites, the origin of which is possibly due to such stars in exactly the same way as the origin of the iron meteorites would be due to stars of the second class.

If this be so, then it would seem that a comet is simply a meteorite which contains something which is volatile at a very low temperature. Amongst the vapours known to chemists, which are volatile at the lowest temperature, are the hydrocarbons. I have already pointed out to you that as far as observations have gone on comets we have been able to detect nothing but the possibility of a spectrum of carbon, or of a compound of carbon.

Here again dimly and darkly the prism is pointing us to a possible connection between all the stars in heaven and all the comets and all the meteors which flit through the celestial spaces and fall upon our own earth.

I have already referred to the verdict of the prism in connection with the nebulæ, and there can be very little doubt, I think, that before the world is very much older the prism will also be perfectly competent to connect nebulæ with stars as it may possibly have already connected comets and meteors with them; but this point certainly is at present one of great difficulty, and it is a difficulty which no student of science will care to get out of, since in matters of this kind a difficulty is a matter of the highest importance, showing you as it does that part of the field of nature which requires most study.

I quite feel that this enormous subject, which modern science is opening up, is one the importance of which is so great and the interest in which is so general that I am sorry that the task of talking about it has not fallen upon the shoulders of one who is more competent to do it than I am. I hope, however, that feeble as my advocacy may have been, you are prepared to agree that the time will come when Celestial Chemistry, as investigated by means of the prism, will be acknowledged to be one of the most important branches of modern science.

J. NORMAN LOCKYER

SCIENTIFIC SERIALS

Journal of the Franklin Institute, February.—In this number Mr. Prindle has a paper (with numerous illustrations) On Recent Improvements in Construction of the Gunpowder Pile-driver.—A long and instructive paper by Mr. Loiseau, On Artificial Fuel, gives a *résumé* of what has hitherto been done in this direction; the author describing his own method, in which a mixture of 5 per cent. clay and 95 per cent. coal-dust, moistened with milk of lime, is moulded into oval lumps, which are then bathed in a waterproofing liquid (rosin dissolved in crude benzine) and dried. With 14 men only, a production of 150 tons per day can, it is said, be easily attained.—Prof. Houston announces the discovery of a new allotropic modification of phosphorus, obtained by boiling good phosphorus repeatedly in potassium hydrate (under certain conditions). This new modification retains for an indefinite time, apparently, the liquid state, even when exposed to temperatures considerably below the melting-point of ordinary phosphorus, from which it also differs in its non-oxidation on exposure to air, and, consequently, its not shining in the dark.—Mr. Chesebrough describes the construction of the Detroit River Tunnel; and Prof. Thurston has a note relative to the estimation of the chemical value of coals containing large quantities of ash.—Among the "Items and Novelties," it is stated that Prof. Thurston has gone very carefully into the subject of a scheme published by Mr. Chesebrough, for keeping canals open in winter by warming the water. The professor's calculations are given, and he finally arrives at an estimate of 5,412,500 dols. as the first cost of apparatus for a canal 350 miles long, 70 feet deep, in the latitude of Central New York; and 1,670,200 dols. for the maintenance per annum. He thinks the scheme deserving of investigation.

Astronomische Nachrichten, Nos. 1,976 and 1,977.—These numbers contain a paper by M. Lohse on the estimation of the depth of sun-spots, and at the same time to ascertain the influence of solar refraction. The principle of his method is as follows:—When a spot having its umbra concentric with penumbra, when seen from the vertical, is seen near the sun's limb, the umbra becomes excentric, and the depth of the umbra p' will be given by the formula $p' = \frac{\epsilon}{\cos \alpha}$ when ϵ is the excentricity and α the heliocentric position-angle of the spot from the axis, and assuming the spot steady, p' should remain constant as α and with it ϵ change. This, however, is found not to be the case, for p' gradually increases as the spot gets from the limb, showing it was raised by refraction at the limb, and therefore this change in the value of p' gives a measure of the sun's refraction. The same author also contributes a paper on the effect of the atmosphere of Venus in the transit over the sun, and he recommends the examination of its atmosphere with the spectroscope for absorption-bands.—J. Hortazzi gives the observations of transits for longitude of Nikolagew.—J. Palisa gives a large numb r of ring-micrometer observations on the minor planets and a few comets.—Dr. Holetschek gives the position of some seventy comparison-stars for planets and comets.—E. Stephan gives a list of ten new nebulæ discovered and observed at Marseilles; all seem excessively small. The elements of the new comet are given by Wilhelm as follows:—

$$\begin{aligned} T &= \text{March } 9\cdot8125 \text{ Berlin time.} \\ \Omega &= 48^\circ\ 17'\ 37''\cdot6 \\ \Pi &= 309^\circ\ 27'\ 46'' \\ i &= 52^\circ\ 29'\ 52''\cdot3 \\ \log. q &= 8\cdot591600 \end{aligned}$$

Memorie della Soc. degli Spectroscopisti Italiani, Oct. and Nov. 1873.—These numbers contain an interesting paper by P. Rosa, assistant at the Observatory at Rome, on the variability of the sun's diameter. He discusses the observations at Greenwich and other places from the year 1750 to 1870, during which time some 13,000 measurements of the solar diameter were made. From these observations he has constructed curves showing the variation of diameter, together with the variation in the number of spots. The agreement of these two curves is not very strong, but on his constructing secondary curves from every fourth year of these primary curves, beginning with any year, the resemblance becomes striking. There are also monthly curves given, showing the mean variation in diameter of the sun for each month, taking a mean of ten years for each curve. These show two maxima in March and September, and two minima in January and June. On examining the curve of variation in diameter, a marked minimum occurs about the year 1792. The author sets forth a theory to account for this variation, that since a comet, when at its perihelion, throws off large quantities of matter, so the sun when at its periastre may throw off matter and become reduced in size, and if such is the case its periastre happened in 1792.—G. Lorenzoni contributes papers on observations on the chromosphere, and on observing contacts in eclipses of the sun with the spectroscope.—G. de Lisa gives observations on solar spots in September, October, and November 1873, made at Palermo, giving a mean of about ten spots a day.—Prof. Young gives a note on the use of M. Rutherford's gratings in the place of prisms for the spectroscope.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 19.—On the Attractions of Magnets and Electric Conductors, by George Gore, F.R.S.

Being desirous of ascertaining whether in the case of two parallel wires conveying electric currents the attractions and repulsions were between the currents themselves or the substances conveying them, and believing this question had not been previously settled, I made the following experiment:—

I passed a powerful voltaic current through the thick copper wire of a large electromagnet, and then divided it equally between two vertical pieces of thin platinum wire of equal diameter and length (about six or seven centimetres), so as to make them equally white hot, the two wires being attached to two horizontal cross wires of copper.

On approaching the two vertical wires symmetrically towards the vertical face of the one pole of the horizontally placed magnet, and at equal distances from it, so that the two downward currents in them might be equally acted upon by the downward and upward portions respectively of the currents which circulated round the magnet-pole, the one was strongly bent towards and the other from the pole, as was, of course, expected; but not the least sign of alteration of relative tempe-

rature of the two wires could be perceived, thereby proving that not even a small proportion of the current was repulsed from the repelled wire, or drawn into the attracted one, as would have occurred had the attraction and repulsion taken place, even to a moderate degree, between the currents themselves; and I therefore conclude that *the attractions and repulsions of electric conductors are not exerted between the currents themselves, but between the substances conveying them.*

Some important consequences appear to flow from this conclusion, especially when it is considered in connection with Ampère's theory of magnetism, and with the molecular changes produced in bodies generally by electric currents and magnetism.

As every molecular disturbance produces an electric alteration in bodies so, conversely, the discoveries of numerous investigators have shown that every electric current passing near or through a substance produces a molecular change, which is rendered manifest in all vessels, liquid conductors, and even in the voltaic arc by the development of sounds, especially if the substances are under the influence of two currents at right angles to each other. In iron it is conspicuously shown also by electro-torsion, a phenomenon I have found and recently made known in a paper read before the Royal Society.

Numerous facts also support the conclusion that the molecular changes referred to last as long as the current. De la Rive has shown that a rod of iron, either transmitting or encircled by an electric current, emits, as long as the current lasts, a different sound when struck; and we know it also exhibits magnetism. The peculiar optical properties of glass and other bodies with regard to polarised light discovered by Faraday also continue as long as the current. A rod of iron also remains twisted as long as it transmits and is encircled by electric currents; and in steel and iron the molecular change (like magnetism) partly remains after the currents cease, and enables the bar to remain twisted.

That the peculiar molecular structure produced in bodies generally by the action of electric currents also possesses a definite direction with regard to that of the current, is shown by the rigidly definite direction of action of magnetised glass and many other transparent bodies upon polarised light; also by the difference of conductivity for heat and for electricity in a plate of iron parallel or transverse to electric currents; by the stratified character of electric discharges in rarefied gases, and the action of electric currents upon it; and especially by the phenomenon of electro-torsion. In the latter example an upward current produces a reverse direction of twist to a downward one, and a right-handed current developes an opposite torsion to a left-handed one; and the two latter are each internally different from the former. As each of these four torsions is an outward manifestation of the collective result of internal molecular disturbance, and possesses different properties, these four cases prove the existence of four distinct molecular movements and four corresponding directions of structure; and the phenomena altogether are of the most rigidly definite character.

As an electric current imparts a definite direction of molecular structure to bodies, and as the attractions and repulsions of electric wires are between the wires themselves and not between the currents, repulsion instead of attraction must be due to *difference of direction of structure* produced by difference of direction of the currents.

Although the Amperean theory has rendered immense service to magnetic science, and agrees admirably with all the phenomena of electro-magnetic attraction, repulsion, and motion, it is in some respects defective; it assumes that magnetism is due to innumerable little electric currents continually circulating in one uniform direction round the molecules of the iron; but there is no known instance of electric currents being maintained without the consumption of power, and in magnets there is no source of power; electric currents also generate heat, but a magnet is not a heated body.

If, however, we substitute the view that the phenomena of attraction and repulsion of magnets are due, not to continuously circulating electric currents, but (as in electric wires) to definite directions of molecular structure, such as is shown by the phenomena of electro-torsion to really exist in them, the theory becomes more perfect. It would also agree with the fact that iron and steel have the power of retaining both magnetism and the electro-torsional state after the currents or other causes producing them have ceased.

According to this view, a magnet, like a spring, is not a source of power, but only an arrangement for storing it up, the power being retained by some internal disposition of its particles acting like a "ratchet," and termed "coercive power." The fact that a magnet becomes warm when its variations of magnetism are great and rapidly repeated, does not contradict this view, because we know it has then, like any other conductor of electricity, electric currents induced in it, and these develop heat by conduction-resistance.

According also to this view any method which will produce the requisite direction of structure in a body will impart to it the capacity of being acted upon by a magnet; and any substance, ferruginous or not, which possesses that structure has that capacity; and in accordance with this we find that a crystal of cyanite (a silicate of alumina) possesses the property, whilst freely suspended, of pointing north and south by the directive influence of terrestrial magnetism, and one of stannite (oxide of tin) points east and west under the same conditions.

Geological Society, March 11.—John Evans, F.R.S., president, in the chair.—The following communications were read:—On the relationship existing between the *Echinothuridæ* Wyville Thomson and the *Perischoechinidæ* McCoy, by R. Etheridge, jun. In this paper the author referred in the first place to the peculiar characters of the genera *Calveria* and *Phormosoma* Wyville Thomson, and especially to those in which they approach the cretaceous genus *Echinothuria* S. P. Woodward, and which led Prof. Wyville Thomson to include these three forms in his group Echinothuridæ. He remarked that an overlapping of the interambulacral plates, more or less like that occurring in these three genera, is met with also in *Archæocidaris* McCoy, and *Lepidechinus* Hall, belonging to the group of palæozoic Echini which McCoy proposed to call Perischoechinidæ, and which is characterised by the presence of more than three rows of plates in the inter-ambulacral areas. As there is no overlapping of these plates in the other genera referred to this group, it includes two types of structure. The author then discussed the characters presented by the test in the genera of the Perischoechinidæ (namely, *Archæocidaris*, *Palæchinus Perischodomus*, *Lepidechinus*, *Eocidaris*, *Melonites*, and *Oligoporus*), and pointed out that although we have no conclusive evidence of the presence of membranous interspaces along with the overlapping plates in *Archæocidaris*, the fragmentary condition in which the remains of that form are usually found would lead us to infer their existence. No known palæozoic genus exhibits the want of distinction between the ambulacra and interambulacra on the ventral half of the test seen in the recent genus *Phormosoma*. In *Melonites* and *Oligoporus* the author described an increase in the number of rows of plates in the ambulacra, and he indicated that all the Perischoechinidæ differ from the later Echini by the increased number of perforations in the ocular and genital plates.—On the discovery of Foraminifera, &c., in the boulder-clays of Cheshire, by William Shone, jun. In this paper the author described the occurrence of Foraminifera, Entomostraca, and some other small organic bodies in the boulder-clay at Newton by Chester and at Dawpool. They were found partly in the interior of specimens of *Turritella terebra*, and partly free in the boulder-clay.—On the occurrence of a Tremadoc area near the Wrekin in South Shropshire, with description of a new fauna, by Charles Callaway. The author stated that in an exposure of light green, micaceous shales dipping south-east at 50° at Shineton near Cressage, which are represented as of Caradoc age in the Geological Survey Map, he found a series of trilobites and other fossils which induced him to regard these Shineton shales as belonging to the Lower Tremadoc series. He described as new species:—*Asaphus eos*, *Conocoryphe salteri*, *C. angulifrons*, *Platypeltis croftii* *Conophrys salopiensis*, *Lichapyge cuspidata*, *Lingulella nicholsoni*, *Metoptoma sabrinæ*, and *Theca lineata*. The author regarded these shales as the equivalents of beds containing *Dictyonema*, found near Malvern and at Pedwardine.

Anthropological Institute, March 24.—Prof. George Busk, F.R.S., president, in the chair.—The President exhibited and described an Ashanti skull. The specimen, with other bones of the body, was taken by Surgeon-Major Gore from an outlying camp which had been deserted on the approach of the British troops. It presented the characteristics rather of a female than a male skull, but Mr. Gore affirmed that he had never heard of the Ashantis carrying about the bones of a woman. Women, in fact, held such an inferior position, that it could scarcely be believed that the Ashantis would take trouble in the preservation of their remains. If the skull exhibited belonged to a man, he could not have been a military leader, but he might have had

such a rank in his tribe as entitled him to the honours that were evidently bestowed on his remains. The paper gave full descriptions and detailed measurements.—A paper was read by Rev. Dunbar I. Heath, On the Origin and Development of the Mental Function in Man. He thought that in the ordinary view the mind is considered as a central essence. Around it is the brain, and still further on the outside the world surrounds the brain. It would conduce towards explaining the facts of mental function if we supposed a material film to coincide with the outside surface of the brain, which might be specialised under the name of Psychoplasm. To that film he would confine mental, as distinguished from cerebral, function; so that the mind would be imaged, not as being the centre, but between brain and world. The paper explained mental growth on that hypothesis.—Mr. W. L. Distant read a paper On the Mental Differences between the Sexes. The question discussed in the paper was—Is there clearly proved to be mental difference between the sexes, and is that difference one of kind or only of degree? Authorities were quoted to show the undoubted physical differences, such as weight of brain, form of skull, &c., also the now moderately well-established fact that in primitive races the hair of women approximates more closely to that of man than obtains in a higher state of civilisation. But it having been clearly proved that the advance of man is shown by a higher form of skull and increase of the cranial capacity, an attempt was made to show some of the conditions that had retarded woman in the mental struggle. The result seemed to prove that the mental divergences might be greatly accounted for—firstly, by sexual selection, difference of education, and force of custom; secondly, by physiological conditions; and that as the race progresses, the cranial capacity of the sexes, though not becoming identical, which is a physical impossibility, will yet become much less distinct and divergent, which is a moral certainty if based on moral conclusions.

Physical Society, March 21.—Dr. J. H. Gladstone, F.R.S., in the chair.—J. H. Fleming, read a paper On the new contact-theory of the Galvanic Cell. After discussing the most recent views regarding the contact and chemical theories, Mr. Fleming exhibited the action of his new battery in which metallic contact of dissimilar metals is completely avoided. The battery consisted of thirty test-tubes of dilute nitric acid alternating with the same number of tubes of sodium pentasulphide, all well insulated. Bent strips of alternate lead and copper connected the neighbouring tubes. By this device the terminal poles are of the same metal. On connecting with a coarse galvanometer, the needle was violently and permanently deflected. Tested by the quadrant electrometer the potential was shown to increase regularly with the number of cells. The sixty cells on first immersion showed an electromotive force exceeding that of Daniell's cells. The principle upon which the action depends is that in the acid lead is positive to copper; in the sulphide it is negative. Mr. Fleming further showed how by using the single fluid nitric acid and the single metal iron, a similar battery could be constructed, provided one-half of each iron strip was rendered passive. In this form also no metallic contacts occurred.—Prof. F. Guthrie illustrated by experiment the distribution of a current of electricity in passing from one pole to another across a conducting medium. This was shown in the case of solids by the stratification of iron filings in the sheets of tin-foil and lead. A current of electricity was passed between two points in a horizontal line lying on the surface of metal placed vertically in the magnetic meridian, and the distribution explored by means of a freely suspended magnet needle. As the needle was gradually lowered its direction of deflection was observed to change at a certain point from east to west. This point was ascertained by experiment to be at a distance below the horizontal line, in which the current entered and left the plate, equal to one-third of the interval between the poles. A similar effect was shown in a liquid conductor.—Prof. G. C. Foster, Dr. Wright, and Dr. Gladstone took part in the discussion of the communications.

Royal Horticultural Society, March 18.—Scientific Committee. Dr. Hooker, P.R.S., in the chair.—The Rev. M. J. Berkeley brought for exhibition Montagne's original drawings of *Artotrogus*. He pointed out that this was only the $\frac{1}{1100}$ inch in diameter, while *Volutella*, with which Mr. W. G. Smith had supposed it might be identical, was from $\frac{1}{300}$ to $\frac{1}{400}$ inch in diameter. Montagne had also found a second species of *Artotrogus*, and of this he showed a drawing. He also remarked that a knowledge of the resting spore of *Peronospora infestans* was a great desideratum. It was to be hoped that, as 100*l*. had been presented to Prof. de Bary to investigate the whole subject, that that would be a matter on which he would throw some light.—Mr. Smee communicated a paper on a disease at present very destructive to *Daphne indica*. Numerous diseased plants were exhibited, and the opinion of the Committee was requested upon them. Prof. Westwood said that as the young leaves of the Daphne were entirely free from acari or the young larvæ of *Coccidæ* or *Aphidæ*, although the adjoining full-grown leaves were much diseased, he was not inclined to regard the disease as originating from the attacks of any of these insects, although it might be due to punctures of some flying species of *Capsidæ*, such as *Phytoxoris campestris*, which attacks the buds and young foliage of the common Chrysanthemum, flying from plant to plant.—Prof. Westwood adverted to the Tea Bug of Assam, which he believed to be identical in Upper India, Java, and Ceylon, and not a new species. The insects of Java were often identical with those of Assam, but he supposed that in this case the insect might have been conveyed from one to the other. Dr. Hooker said that this was very probable. The Ceylon tea-plant was the so-called "hybrid variety" introduced from Assam, and was probably sent from Ceylon to Java.—Prof. Thiselton Dyer exhibited a specimen of an Acacia with a curious white balaniform exudation of insect origin, from the Botanic Garden at Cape Town. Prof. Westwood stated that the insect upon the Acacia was quite new to him, and was closely allied to the *Cionops cataphractus*, a rather rare British insect, allied to the *Coccidæ*; the specimens were females, which had emitted a mass of waxy matter, striated in ridges; the waxen mass was in many places covered with minute larvæ, differing in form from the ordinary larvæ of the *Coccidæ*.

General Meeting.—Mr. H. Little in the chair.—The Rev. M. J. Berkeley called attention to pods ripened in the gardens of Mr. W. Terry, of *Vanilla aromatica* (it has fruited this year abundantly in the Victoria house at Kew); a charming specimen of *Aloe plicatilis*—a miniature tree in form, with fine flowering spikes—came from Mr. J. T. Peacock's collection.

Newcastle

Chemical Society, Feb. 26.—Dr. Lunge, president, in the chair.—A paper was read by Mr. J. Pattinson On the rate at which bleaching powder loses its available chlorine. The examination of a number of samples of bleaching powder, from time to time, during about twelve months, was undertaken with the view of making a contribution towards the solution of this question, "How much available chlorine does bleaching powder lose in a given time?" and also to the further one, "Does weak bleaching powder, say containing 32 per cent. of chlorine, retain its strength better than a stronger bleaching powder?" Three sets of samples were obtained from different manufactories on the Tyne, each set consisting of three samples. It was intended that the three samples of each set should be taken from the same portion of lime—one when it contained about 33 per cent. of available chlorine, one when it contained about 35 per cent., and the third when it contained about 37 per cent.—and with this object the lime was placed in a box in the chlorine chamber, so that it could be easily removed in order to take out the samples at each stage. On examining the tables given in the report it is seen that, with reference to the question as to the relative stability of weak and strong bleaching powder, there is practically no difference in the rate at which they lose available chlorine.

Glasgow

Society of Field Naturalists, March 20.—Annual Meeting.—Mr. J. Allan, vice-president, in the chair.—Mr. P. Cameron, jun., exhibited two sawflies new to Britain: *Blennocampa aterrima* Klug, taken by Dr. Buchanan White at Braemar; *Hoplocampa pectoralis* Thomson, taken by the Rev. T. A. Marshall, F.L.S., at St. Albans. The only recorded locality is Gothland, where it was captured for the first time by Prof. Boheman.—Mr. Cameron also exhibited the two new sawflies described by him in the last number of the *Entomologists' Monthly Magazine*: *Taxonus glottianus*, of which a single specimen was taken at Kenmuir Bank near Glasgow in May; and *Nematus graminis*, a not uncommon species in the district, the larva of which feeds on grasses. The Annual Reports of the Secretary and Treasurer having been read and adopted the Officers and Council for the ensuing year were elected.

Philadelphia

Academy of Natural Sciences, December 2, 1873.—Dr. Ruschenberger, president, in the chair.—Fertilisation of Yucac.

Mr. Thomas Meehan detailed at length the discoveries of Dr. Engelmann and Prof. Riley in regard to the fertilisation of the Yucca by the aid of a small night moth, *Pronuba yuccasella* of Riley, and observed that in this region the fertilisation was effected by this insect every year. In the Rocky Mountains of Colorado in 1871, he saw the *Yucca angustifolia* everywhere seeding in great abundance; but in his journey in 1873 he saw not a solitary seed-vessel in any of the plants, and he suggested that perhaps some periodical insect might take the place of the *Pronuba* in that country.—Note on a Fungoid Root Parasite. Mr. Thomas Meehan exhibited a small Norway spruce, in which the branches and leaves were all of a golden tint. He explained that when plants had little food, or lost their fibres in wet soil by which they could not make use of food, the yellow tint was generally exhibited in the leaves of plants. The similarity of the appearances suggesting, he examined and found the roots thickly enveloped by the mycelia of a fungus, which destroyed the young fibres as fast as they were developed. He had supposed it was one of the small microscopic forms of fungi; but in October of the present year the mycelia developed into a brown agaric with a pileus about two inches broad, but the exact species of which he could not positively determine.

Dec. 9.—Mr. Vaux, vice-president, in the chair.—On the Expansion of the Coma in *Asclepiadaceæ*. Mr. Thomas Meehan exhibited some seed-vessels of *Gonolobus obliquus*, and remarked that, though the hairy appendage to the seed known as the coma in asclepiadaceous plants was of course well understood, he knew of no one who had placed on record any observation in regard to the suddenness of the expansion after the seed left the capsule. It was indeed so very rapid, that the common expression of "like a stroke of lightning," was scarcely an exaggeration. It was only with difficulty that the eye could follow the motion. In the seed-vessel each set of long silky hair was drawn up into a close linear fascicle; but on the instant of the seed being relieved from its case, the coma expanded into a perfect hemisphere. Some of the hair formed a right angle, and others more or less acute ones, each seeming to have its fixed place to fall back to. It was generally supposed that these hairy appendages, and others of a similar character in seeds, were for the express purpose of aiding in seed distribution by wind; but he had failed in so many instances to see the advantages, that it often seemed as if it were the seed profiting by developed organs, rather than that these were especially formed for an express purpose. In the case of the *Gonolobus*, it did seem as if there were better grounds than perhaps in any other case for believing that the hairy appendage is designed expressly to facilitate distribution by wind or air currents. The seeds are heavy, and are borne on the plant but a few feet from the ground; they would fall there in a few seconds on the opening of the capsule, if the mass of hair remained long in its closely compact condition.—On Lingula in a Fish of the Susquehanna. Prof. Leidy.

PARIS

Academy of Sciences, March 23.—M. Bertrand in the chair.—The following communications were read:—Thermal study of the phenomena of solution; reaction of water upon nitric acid, by M. Berthelot. As the result of his investigations the author finds that the heat evolved by the addition of an equivalent of water to acids and bases generally decreases in accordance with a law analogous to a geometrical progression when the equivalents of water (n) increase in arithmetical progression. A formula is obained approaching $Q = \frac{A}{\rho^n}$ where the quantity of heat is Q and ρ, a number near unity. The author discussed the relationship between this formula and the analogous one obtained by M. Becquerel for the electromotive force of acid and alkaline solutions, viz., $= x\,\frac{a}{r^n}$.—On an operation of transfusion of blood performed by M. Béhier at the Hôtel Dieu: note by M. Bouley.—On the origin of the Muscado mace and of mace in general, by M. H. Baillon.—On the pathogenetic rôle of ferments in surgical maladies; new method of treatment for amputations: note by M. A. Guérin.—On the plane distribution of pressures in the interior of isotropic bodies in the state of limited equilibrium; mode of integration of the differential equations: note by M. J. Boussinesq.—On the law of astronomical attraction on the masses of the different bodies of the solar system, and particularly on the mass and duration of the sun, by M. E. Vicaire. The author seems to think it far from being demonstrated that the number called the *mass* of the sun is a real measure of the quantity of matter contained in it.—Programme of a system of geography founded on the exclusive use of decimal measures, of an international meridian 0°, and of stereoscopic and gnomonic projections, by M. B. de Chancourtois.—On the refraction of compressed water, note by M. Mascart.—Reply to the critical observations of M. H. Sainte-Claire Deville, on a method for the determination of vapour densities, by M. Croullebois. The author attempted to defend the apparatus, of which a description had previously been communicated to the Academy.—On the compounds of hydrogen with the alkaline metals, by MM. L. Troost and P. Hautefeuille. The authors have obtained compounds of potassium and sodium with hydrogen, having the formulæ K_2H and Na_2H, and have studied the tensions at every 10° of the hydrogen evolved on heating these compounds from 330° to 430°. K_2H dissolves a further quantity of hydrogen; Na_2H dissolves only a very small quantity of this gas. The authors find that lithium heated to 500° in hydrogen gas at 760 mm. pressure absorbs seventeen times its volume of the gas, while thallium under the same conditions absorbs only three times its volume.—On some bronzes from China and Japan, by M. H. Morin.—On the exotic terrestrial lombricians of the genera Urocheta and Pericheta, by M. E. Perrier.—On some general facts which arise from comparative androgenesis, by M. A. Chatin.—Atmospheric dusts, by M. G. Tissandier. The author has determined the suspended matter in the air of Paris and made analyses of atmospheric dust.—Researches on the formation of superphosphate of lime, by M. J. Kolb.—On the systems of curve-planes, algebraical or transcendental, defined by two characteristics, by M. Fouret.—Explicit condition that a conic may have a fifth-order contact with a given curve, by M. Painvin.—Two new theorems on the wave surface, by M. A. Mannheim.—On a Greek sundial found by M. O. Rayet at Heracleum of Latmos.—On the magnetisation of steel, by M. E. Bouty.—Calorific effects of magnetism in an electro-magnet with several poles, by M. A. Cazin.—Researches on trichloracetates and their derivatives, by M. A. Clermont. The author has obtained trichloracetyl-urea, by acting upon trichloracetate of urea with phosphoric anhydride, and also by the action of trichloracetyl chloride upon urea. The same substance was obtained by this last reaction by Tommasi and Meldola in this country in January.—On some endosmotic properties of the membrane of the shell of birds' eggs, by M. U. Gayon.—On the red colouring-matter of the blood, by M. Béchamp.—On the employment of potassium bisulphate for the distinction of native sulphides, by M. E. Jannettaz.—Observations on the spermatophores of decapod crustacea, by M. Brocchi.—Differentiation of induced and spontaneous movements.—Study of the action of some reputed anæsthetic agents on the functional irritability of the stamens in *Mahonia*, by M. E. Haeckel.—Experimental study upon "ammoniémie," by MM. V. Feltz and E. Ritter.

BRITISH QUADRUPEDS

A History of British Quadrupeds. By Thomas Bell, F.R.S. Second Edition. (Van Voorst).

THIS excellent work having originally appeared in 1839, a second edition in 1874 deserves more than a passing notice. In a country like our own, which has been well populated for so many centuries, and in which the people are increasing at a rate only possible in connection with vast strides in our knowledge of sanitary laws, it is not difficult to form several deductions with regard to the nature of the changes which must be taking place in its fauna, together with their ultimate tendencies. As time progresses, works on the zoology of our island, now not many in number, nor large in size, must dwindle to the proportions of those that might be written on a country like China, in which by degrees nearly every wild species has been exterminated. As there, form after form must die out, giving place to the increase in numbers of the one dominant species, man; till in time a history of British quadrupeds will be better studied from the works of Hume and Lingard than from those of White and Bell. These and other considerations make it a question of more than ordinary importance what stress is to be laid, in scientific investigation, either for the purpose of classification or of minute study on the present geographical distribution of animals. On all sides we see remarks which show most clearly that their authors do not fully realise the true bearing of distribution. They think that it is in opposition to the Darwinian hypothesis; that the camel being found in Africa and Asia, whilst its only close ally, the llama, is a native of the Andes, is a significant fact in favour of the doctrine of "special creation," and the tapirs of Sumatra and South America, only, point in the same direction. But when we begin to realise how the whole fauna of countries can be and have been wholly changed within the extremely brief geologic time of man's existence, and that most palæontological evidence is in the same direction, it is clear that the stress which must be laid on the present distribution of any particular form is not so great as might have been imagined from the results obtained by earlier workers on the subject.

The strong predilection of our countrymen for sport also makes it highly improbable that any important fresh species of terrestrial mammals should be added to our fauna, and so we find that Mr. Bell's second edition includes only a single land animal which is not to be found in the first, namely, *Sorex pigmæus*, the Lesser Shrew, the smallest British mammal, with a total length, tail included, of less than 2½ in. The case is different, however, with respect to the aquatic species which visit our shores. The rapid strides made in our knowledge of the Cetacea by the excellent researches of Prof. Reinhardt. Flower, Turner, and others have considerably increased the number of existing genera and species; and this, taken in connection with the improvement in our powers of identification from the skeleton alone, has added so many as ten well-authenticated species new to our fauna The claims of the Greenland and Atlantic Right whales are however very feeble, and only a single specimen of Cuvier's whale, that described by Prof. Turner from Shetland, is known. Amongst the Phocidæ, also, a specimen obtained by Mr. J. H. Gurney, and identified by Prof. Flower, adds the Ringed Seal; whilst the Hooded Seal has been twice obtained from our eastern coast. Several changes have also had to be made among the Cheiroptera. None have had to be added, but some have been removed, on account of previous imperfect identification. The magnified views of the nose and head of each of our native species at the end of the different chapters, when taken in connection with the carefully compiled tables of measurements, will make it easy for anyone who obtains specimens of these rarely seen animals to identify them without much labour.

Mr. Bell in this edition of his work has, for several reasons, had to avail himself of the assistance of other workers in the same subject, for its completion. The Cheiroptera and Insectivora have been carefully revised and brought up to our present state of knowledge by Mr. R. F. Tomes; but the latter part of the book, including all the new matter on the seals and whales, has been undertaken and most efficiently executed by Mr. E. R. Alston. This latter gentleman, from his acute discriminative powers and persevering industry, has made the portions of the work which it has been his good fortune to superintend the standard literature of the subject on which he treats.

Throughout the book there is an ease and elegance of style which is rarely found, now-a-days, in connection with the frequently but too dryly stated facts of science. This adds an attractiveness to the subject which implants and developes an extra charm in the mind of the reader, leading him on, by its inherent value, to the perusal of page after page, till he has finished the book, and unconsciously acquired an amount of zoological information, that, but for the manner in which it is presented to him, he would never have taken the trouble to acquire. As an example we may quote the description given of the wide-spread superstitions and prejudices which exist with reference to bats in general.

We read, "That the ancient Greek and Roman poets, furnished with exaggerated accounts of the animals infesting the remote regions with which their commerce or their conquests had made them acquainted, should have caught eagerly at those marvellous stories and descriptions, and rendered them subservient to their fabulous but highly imaginative mythology, is not wonderful; and it is more than probable that some of the Indian species of bats, with their predatory habits, their multitudinous numbers, their obscure and mysterious retreats, and the strange combination of the character of beast and bird which they were believed to possess, gave to Virgil the idea, which he has so poetically worked out, of the Harpies which fell upon the hastily-spread tables of his hero and his companions, and polluted whilst they devoured the feast from which they had driven the affrighted guests"—rather active measures for a Pteropine bat, no doubt, but none the less within the limits of human exaggerative powers.

We notice that Mr. Alston, in naming the families of the animals of which he writes, uses the termination -idæ on all occasions, as in Phocidæ, Balaenopteridæ, &c.; but in the earlier part of the work, when the generic name

from which that of the family is derived, ends in -a, the termination -adæ is employed, so that we find the words, Ursidæ, Musteladæ, Talpadæ, &c. With all due deference to Mr. Bell, and in spite of the first line of Lucretius' poem, which commences with "Æneadum genetrix," we cannot help feeling that for the sake of uniformity and the feelings of the many propounders of scientific names who are not so well versed in the dead languages as they might be, it is better to continue the now nearly universally employed -idæ on all occasions.

The illustrations of the species described maintain the general character of the work, some being evidently new, as in the case of the deer. Many chapters have a picturesque and respectively appropriate sketch as a conclusion; and we notice that in the additional chapters, instead of fresh sketches, there are in their place (we say it with regret) views, both in profile and from above, of parts of the skeletons of the subjects of the text.

SCLATER AND SALVIN'S "NOMENCLATOR AVIUM NEOTROPICALIUM"

Nomenclator Avium Neotropicalium, sive avium quæ in Regione Neotropica hucusque repertæ sunt nomina systematicè disposita adjecta sua cuique speciei patria. Accedunt generum et specierum novarum diagnoses. Auctoribus Philippo Lutley Sclater et Osberto Salvin, (Londini: sumptibus auctorum, 1873). 1 vol. fol., 164 pp.

THE naturalists whose names are attached to the present work have been for some years working together on American ornithology. Besides numerous papers and articles of greater or less importance published in the "Ibis," the "Proceedings of the Zoological Society," and elsewhere, they completed in 1869 a quarto volume of "Exotic Ornithology," containing one hundred coloured lithographic plates representing new or rare birds of South and Central America, with accompanying letterpress. These works are understood to be all written with a view to the ultimate incorporation of the results arrived at in an "Index Avium Americanarum," or complete treatise on the ornithology of Central and South America. In further progress towards this end the authors now give us a "Nomenclator" or list of the generic and specific names of the species of birds as yet ascertained by them to occur in these countries, which form the "neotropical region" of Mr. Sclater—one of the six principal regions into which he has proposed to divide the earth's surface zoologically. After the name of each species is added the "patria" or "habitat," indicating the exact locality in which the species has been observed.

The neotropical region is now well known to be the richest in the world, ornithologically speaking; the "Nomenclator" contains the names of no less than 3,565 species of birds which, as the authors have convinced themselves by personal examination, are found in it. About 2,000 of these belong to the great order Passeres, and rather more than 1,500 to the nineteen other orders of birds met with in the neotropical region. One order alone is unrepresented in South and Central America, namely, the Apteryges, which is confined to New Zealand; but on the other hand the neotropical region possesses two peculiar forms of bird-life of ordinal rank (the *Opisthocomus* and the *Tinami*) which are unknown elsewhere. Besides these, many extensive families are entirely restricted to the limits of this region; for instance, the Tanagers with 302 species, the Humming-birds with 387 species, the Dendrocolaptidæ with 217 species, and the Formicariidæ with 211 species. A few Tanagers and Humming-birds have invaded the neighbouring nearctic region (*i.e.* America north of Mexico), but the great bulk of these large groups of birds and of several other less numerous though equally distinct families, is essentially neotropical.

Nor must it be supposed that we are yet by any means fully acquainted with the riches of the neotropical region. The active ornithologists of the day are making continual additions to the long list—chiefly through the exertions of collectors in various parts of the Andean Chain, where almost every valley appears to contain distinct species of birds. At a recent meeting of the Zoological Society, twenty-four new species of birds (several belonging to new genera) were described from a single district in Peru, and Mr. Gould is constantly recording additions to the long series of humming-birds which he has so admirably monographed. Besides this, the anatomy and osteology of the greater number of exotic birds is almost utterly unknown, so that there is ample work in the neotropical region alone for many future generations of ornithologists.

The two collections upon which the "Nomenclator" has been principally based are those of Mr. Sclater and of Messrs. Salvin and Godman. The former of these contains an unrivalled series of the American species of the great order Passeres, and a set of representatives of the other higher orders, down to the end of the parrots—altogether about 7,000 specimens. The latter collection is still larger and more general, embracing the whole series of American birds. It is especially rich in Central American forms, the owners having themselves visited several districts of the Central American Republics, and employed private collectors in other districts for the enrichment of their cabinets.

The "Nomenclator" gives us a summary of all the species represented in these two great collections, and of other species examined by the authors, but of which they have not yet succeeded in obtaining specimens.

In an appendix are added characters of nine new genera, and of thirty-one new species, founded on specimens contained in one or other of the above-mentioned collections.

OUR BOOK SHELF

The Mishmee Hills; an Account of a Journey made in an Attempt to penetrate Thibet from Assam to open new Routes for Commerce. By T. T. Cooper, F.R.G.S., Acting Political Agent at Bhamo. (London: Henry S. King and Co., 1873.)

MR. COOPER is already well known as an enterprising traveller and delightful story-teller through his "Travels of a Pioneer of Commerce in Pig-tail and Petticoats;" the present narrative is one of the most attractive published for a long time; it is one of the few books now published one feels inclined to read through at a sitting. Mr. Cooper tells his story without apparent effort, and in

simple, unaffected style. For many centuries China has had the monopoly of supplying the Thibetans with tea, of which they are most extensive consumers. The Lamas of Thibet have the exclusive privilege of retailing this tea, and both they and the Chinese naturally do all in their power to prevent the possibility of any rivalry in the lucrative trade. It was on this account that Mr. Cooper was prevented from completing his intended journey from Shanghai overland to India. In the present work the author describes an attempt which he made to penetrate into Thibet from the Indian side, for the purpo e of discovering whether it would not be possible to open up a way for the introduction into that country of the abundant produce of the Assam tea-plantations. He proceeded from Calcutta to Sudiya, on the north-east frontier of Assam, from which, after making all due preparations, he set out on his adventurous journey in the latter part of 1869. Notwithstanding that Mr. Cooper was accompanied by a Khamtee chief, Chowsam—a fine manly fellow—who knew the country well, and was feared and respected by the people through whose country Mr. Cooper had to pass, the latter, amid great hardships, succeeded in penetrating north-eastward along the Brahmapootra, only about 100 miles, when, through the determined opposition of the Thibetan officials, he was compelled to turn back. No doubt Mr. Cooper failed in accomplishing the object on which he had set his heart, but his journey has been the means of giving to the world a book full of interesting information about the peoples and the countries where he sojourned, both in Assam and the districts just beyond its north-eastern frontier. The book contains a great deal of information on the present and past condition of Assam and the Assamese, and much information on the state of the tea-cultivation in that country. Mr. Cooper is particularly observant of men and manners, and most readers will find in his book a great deal that is quite new concerning the small tribes that live along the route by which he attempted, in the interest of commerce, to enter Thibet; his description of the Khamtees is especially interesting. Mr. Cooper does not pretend to give any scientific record of the natural history of the country through which he passed, though he makes occasional observations that may interest naturalists. The following description of the land-leeches which pestered him during his journey, seems to us particularly interesting:—

"Of all the hardships and unpleasant sensations experienced in the Assam jungle none have left a more disagreeable recollection than the attacks of land-leeches. Often, on sitting down, I could count a dozen of these little animals hurrying from all directions to their prey. In length they are about an inch, while their thickness does not exceed that of an ordinary sewing needle. Their mode of progression is curious in the extreme. Fixing one extremity by means of its bell-shaped sucker firmly on a leaf or on the ground, the leech curves itself into an arch, the other end is then advanced till the creature resembles a loop, again to expand into an arch, but the movement is quicker than words can describe it; the rapidity with which they thus progress along is quite startling. As they occasionally rear themselves perpendicularly and sway about from side to side, taking a survey round them in quest of prey, the observer cannot fail to conceive a dread of the bloodthirsty little creatures. They exercised quite a fascination over me. I could never resist watching them whenever I took a seat. Their power of scent was evidently keen. At first they would hold themselves erect, then suddenly, as though they had just discovered my whereabouts, they would throw themselves forward and with quick eager strides make towards my unfortunate body, and it was a long time before I could restrain a shudder at their approach, but use does wonders, and at last I used to flip them off my clothes and hands, Khamtee fashion, with great indifference. There are several species of leeches in Assam, but I have only come in contact with three kinds: the common brown one, just described; the red, or hill leech, which is larger than the former and of a light red colour, inflicting a venomous, though not dangerous, bite; and the hair-leech, so called by the Khamtees from its great length and extreme tenuity. This last description of leech lies in wait in the grass, and as animals feed it enters the nostrils and fixes itself firmly in the interior, where it takes up permanent quarters, causing the poor beasts great irritation. It seems to inflict itself entirely on animals, which is fortunate, or man would suffer greatly from this scourge of the jungle."

Mr. Cooper has done well in telling the world the story of his travels.

Transactions of the Albany Institute, vol. vii. (Albany, U.S., 1872.)

THIS institution is one of the oldest of its kind in America, having been originally founded upwards of eighty years ago, just after the conclusion of the American War of Independence. At present it is one of the most comprehensive and active of the American societies, its sphere of work embracing all departments of literature and science. In an eloquent annual address, which is the first paper in this volume, Orlando Meads, one of the oldest members of the Institute, sketches its history, and gives reminiscences of some of the most eminent men who have been connected with the Society, including several who have left their mark on the country. A characteristic feature of this volume is the reports of what has been done during the year, both in America and Europe, in the various divisions of science and literature, the institution being divided into three departments—Physical Sciences and the Arts, Natural History, and History and General Literature, and these again into a number of classes. Thus we have in the present volume, reports on botany, zoology, chemistry, and general literature. Of the papers in this volume we may notice one On Nitro-glycerine, as used in the construction of the Hoosac Tunnel, by Prof. G. M. Mowbray. The author traces the history of the dangerous article, gives an account of his own investigations regarding it, and describes the method in which it was used in boring the Hoosac tunnel.—On certain new Phenomena in Chemistry, by Verplanck Colvin, describes some very remarkable experiments in amalgamation made by the author. From Newton to Kirchoff, by Dr. L. C. Cooley, traces in an interesting way the progress of research on Light during the period indicated; and in Researches in the Theory and Calculus of Operations, by J. A. Paterson, we have a most elaborate and intricate investigation on the theory of the actions of various forces of Nature. Mr. C. H. Peck contributes a Synopsis of New York Uncinulæ.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Microscopic Examination of Air

IN support of the conclusions arrived at by Mr. Douglas Cunningham, of Calcutta, in his "Microscopic Examinations of Air" (NATURE, vol. ix. p. 330), and in illustration of the method which he employed, perhaps I may be allowed to describe some observations of the same kind which I made three years ago but have not had leisure to continue or prepare for publication.

A sentence in Dr. Parkes' "Manual of Hygiene," alluding to the importance of minute examination of the air, turned my thoughts in that direction. The instrument which I constructed for the purpose was contrived after the manner of a weathercock, presenting the wide mouth of a funnel to the wind, while the

tube of the funnel was bent upwards and had an orifice about 1-20th of an inch in diameter. Close above this orifice was placed a glass slide, held by springs and bearing a drop of glycerine on its lower surface. The tube and glass slide were protected by a roof and two cheek-boards, which formed the vane of the weather-cock. The glass slide was so placed that the current of air issuing from the narrow orifice of the bent tube, under pressure of the wind on the wide mouth of the funnel, impinged on the centre of the drop of glycerine, and a large proportion of any solid matters carried by the air was caught on the glycerine. After a day or two, according to the weather, the slide was removed, a thin disk of glass was placed on the glycerine-drop, and the contents were then examined under the microscope, a duplicate slide being left in the aeroscope for the next observation.

This instrument depended for its function on the wind. If there was no wind, there was no current through the tube, and nothing was caught on the glycerine; but in general there was wind enough, and the captures were ample, often embarrassing by their multitude. The observations were mostly made in the neighbourhood of London, at the Greenwich Observatory. The nature of the captures varied according to the direction and velocity of the wind, the state of the weather, and the season of the year. A north-west wind, blowing over London, brought soot and globules of coal-tar, textile fibres, nondescript *débris*, a few vegetable spores, now and then an epithelial scale or two, always a number of half-cooked starch-grains (identified by their reaction with iodine and by traces of concentric lamination giving a black cross with the polariscope), and sometimes microscopic bread-crumbs (half-cooked starch-grains in meshes of gluten). The starch-grains were the most constant capture of all, in all seasons and for all directions of wind. They seem to be very durable. (If I remember rightly, M. Pouchet found starch-grains in all specimens of dust, even the most ancient, obtained from the neighbourhood of human dwellings.) A southerly wind, blowing from the country, brought a great variety of vegetable spores and pollen-grains and *débris*, with a smaller proportion of matters characteristic of town air. The size and quantity of the captures depended mainly on the velocity of the wind. Once or twice a strong wind swept a living acarus, or an entomostracan, or the shell of a diatom into the glycerine. In dry windy weather a quantity of siliceous sand was caught, which gave trouble by tilting the disk when in preparation for the microscope, and the larger grains had to be removed with the point of a needle.

The most interesting variation in the character of the organic captures was that which depended on the season of the year. In January and February scarcely anything was found (besides *débris* and inorganic matter) but a few fragments of mycelium of some fungus; but with the first fine weather in March the glycerine began to yield good returns. Spherical grains of poplar pollen were caught in large numbers, thirty or forty in a single drop, though the nearest poplar tree was a quarter of a mile distant. These were soon followed by the triangular pollen of birch and hazel—trees depending, like poplar, on the agency of the wind for fertilisation. From this time onward, through spring and summer, a great number and variety of pollen grains were caught. Cryptogamic cells increased in number through the summer, and reached their maximum in the autumn, when brown septate spores and others of various kinds, which my imperfect knowledge did not enable me to identify, appeared in abundance. If left for some days, they began to germinate. Towards winter their number diminished, the latest being minute dark brown oval spores of some species of agaricus (?). The winter months were comparatively barren.

I did not find any Bacteria, but there were numbers of excessively minute particles, of which I could not tell the nature. Once, after leaving the aeroscope for several days, I found the glycerine swarming with a minute *torula* which had evidently multiplied in that pabulum. In fact the glycerine was fermenting.

Among these facts, the only one which seems to have any bearing on the question of the propagation of infectious diseases is the great prevalence of cryptogamic spores in the air in autumn, when those diseases are especially rife.

To avoid fallacy in the results obtained, I used to place two drops of glycerine on the same slide, but only directed the air-current against one of them; both were examined under the microscope, and the difference credited to the air. By using glycerine that had been boiled with carmine, many of the organic captures were made more distinct: the nuclei of epithelial scales and of many other cells were brightly stained by the carmine. Glycerine had the disadvantage of absorbing moisture in damp weather and swelling to an inconvenient bulk. At such times I used oil instead, with good effect. My plan of examination was to sweep the whole disk in successive parallel zones, by the aid of mechanical stage-movement, and make record of every organic body that could be recognised. Such as I had not seen before were sketched with pen and ink and coloured chalk in a book devoted to that purpose.

It will be seen that my observations entirely support Mr Cunningham's, as to the abundant presence of living spores in the air. I was satisfied that this branch of research, in the hands of one thoroughly familiar with these microscopic forms, would lead to results of great interest, and I heartily congratulate Mr. Cunningham on the valuable work which he has produced.

HUBERT AIRY

Animal Locomotion

MR. WALLACE'S last letter seems to call for a word of explanation from me. I did not refer to the up stroke of the bird's wing because this was not the point in dispute. But in reply to Mr. Wallace's latest stricture—that I appear "to ignore the great downward reaction, added to gravitation, during every up stroke"—I would say (1) that the downward reaction is not great, (*a*) because, as Mr. Wallace has himself observed, of the valvular action of the feathers; (*b*) because of the convex form of the upper surface of the wing; and (*c*) in some cases, because the wing is less expanded in the up stroke. (2) As to the effect of gravitation, this was already allowed for in determining the resultant motion consequent on the down stroke, and must not be reckoned twice. Just as with an arrow shot from a bow, so with the bird; the motion consequent on the down stroke lasts long enough for the wings to be raised before it is spent. Mr. Wallace is certainly right in saying that the down stroke should counteract the downward reaction of the up stroke, but this downward reaction being slight cannot require "a highly-inclined upward motion," and what is more, it cannot require that the under surface of the wing should be directed forwards as Dr. Pettigrew asserts.

Again, I do not say the movement of the wing as a whole is downward and backward, but that the action of its surface is in that direction. The Duke of Argyll is no doubt correct in maintaining that the wing as a whole moves in a perpendicular line, or perhaps with a slight forward overlap.

I cordially agree with Mr. Wallace that the matter is not to be settled by "discussing theoretically, but by observation and experiment;" still the elementary principles of mechanics may surely be heard in evidence without disadvantage even at the outset of the inquiry.

Trinity College, Cambridge, March 30

Rudimentary Organs

IN a former communication (NATURE, vol. ix. p. 361) I promised to advance what seems to me a probable cause—additional to those already known—of the reduction of useless structures. As before stated, it was suggested to me by the penetrating theory proposed by Mr. Darwin (NATURE, vol. viii. pp. 432 and 505), to which, indeed, it is but a supplement. Epitomising Mr. Darwin's conception as to the dwarfing influence of impoverished conditions, progressively reducing the average size of a useless structure, by means of free intercrossing; the present cause may be defined as the mere cessation of the selective influence from changed condition of life.

Suppose a structure to have been raised by natural selection from 0 to average size 100, and then to have become wholly useless. The selective influence would now not only be withdrawn, but reversed; for, through Economy of Growth—understanding by this term both the direct and the indirect influence of natural selection*—it would rigidly eliminate the variations 101, 102, 103, &c., and favour the variations 99, 98, 97, &c. For the sake of definition we shall neglect the influence of Economy acting below 100, and so isolate the effects due to the mere withdrawal of Selection. By the condition of our assumption, all variations above 100 are eliminated, while below 100 indiscrimi-

* See former communication, NATURE, vol. ix. p. 361.

nate variation is permitted. Thus, the selective premium upon variation 99 being no greater than that upon 98, 98 would have as good a chance of leaving offspring (which would inherit and transmit this variation) as would 99: similarly, 97 would have as good a chance as 98, and so on. Now there is thus a much greater chance of variations being perpetuated at or below 99, than at or above 100; for at 100 the hard line of Selection (or Economy) is fixed, while there is no corresponding line below 100. The consequence of free intercrossing would therefore be to reduce the average from 100 to 99. Simultaneously, however, with this reducing process, other variations would be surviving below 99, in greater numbers than above 99; consequently the average would next become reduced to 98. There would thus be "two operations going on side by side—the one ever destroying the symmetry of distribution" round the average, "and the other ever tending to restore it." It is evident, however, that the more the average is reduced by this process of indiscriminate variation, the less chance there remains for its further reduction. When, for instance, it falls to 90, there are (numerically, though not actually, because of Inheritance) 89 to 9 in favour of diminution; but, when it falls to 80, there are only 79 to 19 in such favour. Thus (theoretically) the average would continue to diminish at a slower and slower rate, until it comes to 50, where, the chances in favour of increase and of diminution being equal, it would remain stationary.

Having thus, for the sake of clearness, considered this principle apart, let us now observe the effect of superadding to it the influence of the Economy of Growth—a principle with which its action must always be associated. Briefly, as this influence would be that of continually favouring the variations on the side of diminution, the effect of its presence would be that of continuously preventing the average from becoming fixed at 50, 40, 30, &c. In other words, the "hard line of Selection," which was originally placed at 100, would now become progressively lowered through 90, 80, 70, &c.; always allowing indiscriminate variation below the barrier, but never above it.

It will be understood that by "cessation of selection from changed conditions of life" I mean a change *of any kind* which renders the affected organ superfluous. Take, for example, the exact converse of Mr. George Darwin's illustration, by supposing a herd of cattle to migrate from a small tract of poor pasture to a large tract of rich. Segregation would ensue, the law of battle would become less severe, while variation would be promoted in a cumulative manner by the increase of food. The young males with shorter horns would thus have as good a chance of leaving progeny as "their longer-horned brothers," and the average length would gradually diminish as in the other case. Of course, as the predisposing cause of impoverished nutrition would now be absent, the reducing process would take place at a slower rate. Moreover, it is to be remarked that this principle differs in an important particular from that enunciated by Mr. Darwin, in that it could never reduce an organ much below the point at which the Economy of Growth (together with Disuse) ceases to act. For, returning to our numerical illustration, suppose this point to be 6, the average would eventually become fixed at 3.

That the principle thus explained has a real existence we may safely conclude, theoretical considerations apart, from the analogy afforded by our domestic races; for nothing is more certain to breeders than the fact that neglect causes degeneration, even though the strain be kept isolated. It will be observed that, if this principle has a real existence, it is of considerable importance, theoretically, since it must act, to a greater or less extent, in all cases where Disuse and the Economy of Growth are in operation; and although in the initial stages of reduction, when the purchase, so to speak, of the last-named principle is great, its influence would be comparatively trivial, this influence would be more and more felt the smaller the organ became—*i.e.*, the nearer the point at which the Economy of Growth ceases to act. The Cessation of Selection should therefore be regarded as a reducing cause, which co-operates with other reducing causes in all cases, and which is of special importance as an accelerating agent when the influence of the latter becomes feeble.

GEORGE J. ROMANES

Lakes with two Outfalls

ON June 22, 1863, the late Captain Speke published his map, giving (on native authority) *four* outlets from Lake Victoria Nyanza, converging to *one* valley or water-flow—the Nile.

On June 27 and on July 20 I wrote to the *Athenæum*:—"I think that this native information will prove to be erroneous;" that I thought "that no lake can have more than one outlet;" and I added, "May I lay the question as to the matter of fact before the readers of the *Athenæum*?" In reply, the Black Loch in Dumfriesshire was stated to have *two* outlets to *two* distinct valleys or water-flows—one to the Nith, the other to the Ayr. The Loch, however, has but one outlet, and that *artificial*. The water-parting has been cut through by man—a mill-lead made to Lord Bute's Borland mill, and the one outlet is an iron sluice in a stone dam. All this is beautifully shown in Sir Henry James's admirable 25-inch Ordnance Maps.

Dr. Bryce ("Geology of Arran," 3rd edition, p. 3) says that Loch-an-Davie has two outlets to two different valleys. It has, however, but one outlet, to the south—to Glen Iorsa, as I stated in the *Athenæum*, July 22, 1865. The new inch Ordnance Map of Arran gives one outlet, but unfortunately to the north, instead of to the south. I will not refer to my letter on the two outlets to two valleys from the Norwegian Lesjeskaugen Lake, which you did me the honour to publish last September, and with which Prof. Stanley Jevons agreed. But I quote the above cases to show that even the highest authorities make mistakes as regards lakes and their outlets. I cannot, however, suppose any mistake in Prof. Bell's account of the two outlets to two valleys from Shoal Lake, published in NATURE, vol. ix. p. 363, by Prof. Dawson. I would then, in deference to these authorities, modify my dictum by saying, that if by a rare possibility a lake may be found to exist on a water-parting having at opposite ends two outlets to two different valleys, I should still doubt the possibility of a lake at its one lower end having a multiplicity of outlets converging to one valley or water-flow, as in the case of the Victoria Nyanza. And this owing to the extreme improbability that the erosion at each outlet should continue at precisely the same rate.

The outlet of every lake in the wide, wide world is always being lowered from erosion, as are valleys themselves. Valleys exist only in the dissolution of hills. They are mere water-flows. They are the perpetually changing effects of atmospheric disintegration, and the erosion of rain and rivers, and consequently every water-parting is a valley-parting.

Alresford, March 14 GEORGE GREENWOOD

A Beech pierced by a Thorn Plant

ON the road from this to Belfast there is a thorn hedge with beech trees at intervals, and thorn plants have grown right through the middle of the trunks of two of the beeches. I do not know whether this is sufficiently uncommon to be worth mentioning in NATURE. JOSEPH JOHN MURPHY

Old Forge, Dunmurry, co. Antrim

KINETIC THEORY OF THE DISSIPATION OF ENERGY

IN abstract dynamics an instantaneous reversal of the motion of every moving particle of a system causes the system to move backwards, each particle of it along its old path, and at the same speed as before when again in the same position—that is to say, in mathematical language, any solution remains a solution when t is changed into $-t$. In physical dynamics, this simple and perfect reversibility fails on account of forces depending on friction of solids; imperfect fluidity of fluids; imperfect elasticity of solids; inequalities of temperature and consequent conduction of heat produced by stresses in solids and fluids; imperfect magnetic retentiveness; residual electric polarisation of dielectrics; generation of heat by electric currents induced by motion; diffusion of fluids, solution of solids in fluids, and other chemical changes; and absorption of radiant heat and light. Consideration of these agencies in connection with the all-pervading law of the conservation of energy proved for them by Joule, led me twenty-three years ago to the theory of the dissipation of energy, which I communicated first to the Royal Society of Edinburgh in 1852, in a paper entitled

"On a Universal Tendency in Nature to the Dissipation of Mechanical Energy.

The essence of Joule's discovery is the subjection of physical phenomena to dynamical law. If, then, the motion of every particle of matter in the universe were precisely reversed at any instant, the course of nature would be simply reversed for ever after. The bursting bubble of foam at the foot of a waterfall would reunite and descend into the water: the thermal motions would reconcentrate their energy and throw the mass up the fall in drops reforming into a close column of ascending water. Heat which had been generated by the friction of solids and dissipated by conduction, and radiation with absorption, would come again to the place of contact and throw the moving body back against the force to which it had previously yielded. Boulders would recover from the mud the materials required to rebuild them into their previous jagged forms, and would become reunited to the mountain peak from which they had formerly broken away. And if also the materialistic hypothesis of life were true, living creatures would grow backwards, with conscious knowledge of the future, but no memory of the past, and would become again unborn. But the real phenomena of life infinitely transcend human science, and speculation regarding consequences of their imagined reversal is utterly unprofitable. Far otherwise, however, is it in respect to the reversal of the motions of matter uninfluenced by life, a very elementary consideration of which leads to the full explanation of the theory of dissipation of energy.

To take one of the simplest cases of the dissipation of energy, the conduction of heat through a solid—consider a bar of metal warmer at one end than the other and left to itself. To avoid all needless complication, of taking loss or gain of heat into account, imagine the bar to be varnished with a substance impermeable to heat. For the sake of definiteness, imagine the bar to be first given with one half of it at one uniform temperature, and the other half of it at another uniform temperature. Instantly a diffusing of heat commences, and the distribution of temperature becomes continuously less and less unequal, tending to perfect uniformity, but never in any finite time attaining perfectly to this ultimate condition. This process of diffusion could be perfectly prevented by an army of Maxwell's "intelligent demons"* stationed at the surface, or interface as we may call it with Prof. James Thomson, separating the hot from the cold part of the bar. To see precisely how this is to be done, consider rather a gas than a solid, because we have much knowledge regarding the molecular motions of a gas, and little or no knowledge of the molecular motions of a solid. Take a jar with the lower half occupied by cold air or gas, and the upper half occupied with air or gas of the same kind, but at a higher temperature, and let the mouth of the jar be closed by an air-tight lid. If the containing vessel were perfectly impermeable to heat, the diffusion of heat would follow the same law in the gas as in the solid, though in the gas the diffusion of heat takes place chiefly by the diffusion of molecules, each taking its energy with it, and only to a small proportion of its whole amount by the interchange of energy between molecule and molecule; whereas in the solid there is little or no diffusion of substance, and the diffusion of heat takes place entirely, or almost entirely, through the communication of energy from one molecule to another. Fourier's exquisite mathematical analysis expresses perfectly the statistics of the process of diffusion in each case, whether it be "conduction of heat," as Fourier and his followers have called it, or the diffusion of substance in fluid masses (gaseous or liquid) which Fick showed to be subject to Fourier's formulæ. Now, suppose the weapon of the ideal army to be a club, or, as it were, a molecular cricket-bat; and suppose for convenience the mass of each demon with his weapon to be several times greater than that of a molecule. Every time he strikes a molecule he is to send it away with the same energy as it had immediately before. Each demon is to keep as nearly as possible to a certain station, making only such excursions from it as the execution of his orders requires. He is to experience no forces except such as result from collisions with molecules, and mutual forces between parts of his own mass, including his weapon: thus his voluntary movements cannot influence the position of his centre of gravity, otherwise than by producing collision with molecules.

The whole interface between hot and cold is to be divided into small areas, each allotted to a single demon. The duty of each demon is to guard his allotment, turning molecules back or allowing them to pass through from either side, according to certain definite orders. First, let the orders be to allow no molecules to pass from either side. The effect will be the same as if the interface were stopped by a barrier impermeable to matter and to heat. The pressure of the gas being, by hypothesis, equal in the hot and cold parts, the resultant momentum taken by each demon from any considerable number of molecules will be zero; and therefore he may so time his strokes that he shall never move to any considerable distance from his station. Now, instead of stopping and turning all the molecules from crossing his allotted area, let each demon permit a hundred molecules chosen arbitrarily to cross it from the hot side; and the same number of molecules, chosen so as to have the same entire amount of energy and the same resultant momentum, to cross the other way from the cold side. Let this be done over and over again within certain small equal consecutive intervals of time, with care that if the specified balance of energy and momentum is not exactly fulfilled in respect to each successive hundred molecules crossing each way, the error will be carried forward, and as nearly as may be corrected, in respect to the next hundred. Thus, a certain perfectly regular diffusion of the gas both ways across the interface goes on, while the original different temperatures on the two sides of the interface are maintained without change.

Suppose, now, that in the original condition the temperature and pressure of the gas are each equal throughout the vessel, and let it be required to disequalise the temperature but to leave the pressure the same in any two portions A and B of the whole space. Station the army on the interface as previously described. Let the orders now be that each demon is to stop all molecules from crossing his area in either direction except 100 coming from A, arbitrarily chosen to be let pass into B, and a greater number, having among them less energy but equal momentum, to cross from B to A. Let this be repeated over and over again. The temperature in A will be continually diminished and the number of molecules in it continually increased, until there are not in B enough of molecules with small enough velocities to fulfil the condition with reference to permission to pass from B to A. If after that no molecule be allowed to pass the interface in either direction, the final condition will be very great condensation and very low temperature in A; rarefaction and very high temperature in B; and equal temperature in A and B. The process of disequalisation of temperature and density might be stopped at any time by changing the orders to those previously specified (2), and so permitting a certain degree of diffusion each way across the interface while maintaining a certain uniform difference of temperatures with equality of pressure on the two sides.

If no selective influence, such as that of the ideal "demon," guides individual molecules, the average result of their free motions and collisions must be to equalise the distribution of energy among

* The definition of a "demon," according to the use of this word by Maxwell, is an intelligent being endowed with free will, and fine enough tactile and perceptive organisation to give him the faculty of observing and influencing individual molecules of matter.

them in the gross; and after a sufficiently long time from the supposed initial arrangement the difference of energy in any two equal volumes, each containing a very great number of molecules, must bear a very small proportion to the whole amount in either; or, more strictly speaking, the probability of the difference of energy exceeding any stated finite proportion of the whole energy in either is very small. Suppose now the temperature to have become thus very approximately equalised at a certain time from the beginning, and let the motion of every particle become instantaneously reversed. Each molecule will retrace its former path, and at the end of a second interval of time, equal to the former, every molecule will be in the same position, and moving with the same velocity, as at the beginning; so that the given initial unequal distribution of temperature will again be found, with only the difference that each particle is moving in the direction reverse to that of its initial motion. This difference will not prevent an instantaneous subsequent commencement of equalisation, which, with entirely different paths for the individual molecules, will go on in the average according to the same law as that which took place immediately after the system was first left to itself.

By merely looking on crowds of molecules, and reckoning their energy in the gross, we could not discover that in the very special case we have just considered the progress was towards a succession of states in which the distribution of energy deviates more and more from uniformity up to a certain time. The number of molecules being finite, it is clear that small finite deviations from absolute precision in the reversal we have supposed would not obviate the resulting disequalisation of the distribution of energy. But the greater the number of molecules, the shorter will be the time during which the disequalising will continue; and it is only when we regard the number of molecules as practically infinite that we can regard spontaneous disequalisation as practically impossible. And, in point of fact, if any finite number of perfectly elastic molecules, however great, be given in motion in the interior of a perfectly rigid vessel, and be left for a sufficiently long time undisturbed except by mutual impacts and collisions against the sides of the containing vessel, it must happen over and over again that (for example) something more than nine-tenths of the whole energy shall be in one half of the vessel, and less than one-tenth of the whole energy in the other half. But if the number of molecules be very great, this will happen enormously less frequently than that something more than 6-10ths shall be in one half, and something less than 4-10ths in the other. Taking as unit of time the average interval of free motion between consecutive collisions, it is easily seen that the probability of there being something more than any stated percentage of excess above the half of the energy in one half of the vessel during the unit of time, from a stated instant, is smaller the greater the dimensions of the vessel and the greater the stated percentage. It is a strange but nevertheless a true conception of the old well-known law of the conduction of heat to say that it is very improbable that in the course of 1,000 years one half the bar of iron shall of itself become warmer by a degree than the other half; and that the probability of this happening before 1,000,000 years pass is 1,000 tines as great as that it will happen in the course of 1,000 years, and that it certainly will happen in the course of some very long time. But let it be remembered that we have supposed the bar to be covered with an impermeable varnish. Do away with this impossible ideal, and believe the number of molecules in the universe to be infinite; then we may say one half of the bar will never become warmer than the other, except by the agency of external sources of heat or cold. This one instance suffices to explain the philosophy of the foundation on which the theory of the dissipation of energy rests.

Take however another case in which the probability may be readily calculated. Let a hermetically-sealed glass jar of air contain 2,000,000,000,000 molecules of oxygen, and 8,000,000,000,000 molecules of nitrogen. If examined any time in the infinitely distant future, what is the number of chances against one that all the molecules of oxygen and none of nitrogen shall be found in one stated part of the vessel equal in volume to 1-5th of the whole? The number expressing the answer in the Arabic notation has about 2,173,220,000,000 of places of whole numbers. On the other hand the chance against there being exactly 2-10ths of the whole number of particles of nitrogen, and at the same time exactly 2-10ths of the whole number of particles of oxygen in the first specified part of the vessel is only 4021×10^9 to 1.

[*Appendix.—Calculation of Probability respecting Diffusion of Gases.*]

For simplicity I suppose the sphere of action of each molecule to be infinitely small in comparison with its average distance from its nearest neighbour: thus, the sum of the volumes of the spheres of action of all the molecules will be infinitely small in proportion to the whole volume of the containing vessel. For brevity, space external to the sphere of action of every molecule will be called free space: and a molecule will be said to be in free space at any time when its sphere of action is wholly in free space; that is to say, when its sphere of action does not overlap the sphere of action of any other molecule. Let A, B denote any two particular portions of the whole containing vessel, and let a, b be the volumes of those portions. The chance that at any instant one individual molecule of whichever gas shall be in A is $\frac{a}{a+b}$, however many or few other molecules there may be in A at the same time; because its chances of being in any specified portions of free space are proportional to their volumes; and, according to our supposition, even if all the other molecules were in A, the volume of free space in it would not be sensibly diminished by their presence. The chance that of n molecules in the whole space there shall be i stated individuals in A, and that the other $n-i$ molecules shall be at the same time in B, is

$$\left(\frac{a}{a+b}\right)^i \left(\frac{b}{a+b}\right)^{n-i}, \text{ or } \frac{a^i b^{n-i}}{(a+b)^n}$$

Hence the probability of the number of molecules in A being exactly i, and in B exactly $n-i$, irrespectively of individuals, is a fraction having for denominator $(a+b)^n$, and for numerator the term involving $a^i b^{n-i}$ in the expansion of this binomial; that is to say it is—

$$\frac{n(n-1)\;.\;.\;.\;.\;(n-i+1)}{1.2\;\;.\;.\;.\;.\;\;i} \left(\frac{a}{a+b}\right)^i \left(\frac{b}{a+b}\right)^{n-i}$$

If we call this T_i we have

$$T_{i+1} = \frac{n-i}{i+1}\frac{a}{b}\,T_{i+1}$$

Hence T_i is the greatest term if i is the smallest integer which makes

$$\frac{n-i}{i+1} < \frac{b}{a}$$

this is to say, if i is the smallest integer which exceeds

$$n\frac{a}{a+b} - \frac{b}{a+b}$$

Hence if a and b are commensurable the greatest term is that for which

$$i = n\frac{a}{a+b}$$

To apply these results to the cases considered in the preceding article, put in the first place

$$n = 2 \times 10^{12}$$

this being the number of particles of oxygen; and let $i = n$. Thus, for the probability that all the particles of oxygen shall be in A, we find

$$\left(\frac{a}{a+b}\right)^{8 \times 10^{12}}$$

Similarly, for the probability that all the particles of nitrogen are in the space B, we find

$$\left(\frac{b}{a+b}\right)^{2\times10^{12}}$$

Hence the probability that all the oxygen is in A and all the nitrogen in B is

$$\left(\frac{a}{a+b}\right)^{2\times10^{12}}\times\left(\frac{b}{a\times b}\right)^{8\times10^{12}}$$

Now by hypothesis

$$\frac{a}{a+b}=\frac{2}{10}$$

and therefore

$$\frac{b}{a+b}=\frac{8}{10}$$

hence the required probability is

$$\frac{2^{26\times10^{12}}}{10^{10^{13}}}$$

Call this $\frac{1}{N}$, and let log denote common logarithm. We have $\log N = 10^{13} - 26\times10^{12}\times\log.\,2 = (10 - 26\log.\,2)\times10^{12} = 2173220\times10^{6}$. This is equivalent to the result stated in the text above. The logarithm of so great a number, unless given to more than thirteen significant places, cannot indicate more than the number of places of whole numbers in the answer to the proposed question, expressed according to the Arabic notation.

The calculation of T_i when i and $n-i$ are very large numbers is practicable by Stirling's Theorem, according to which we have approximately

$$1.2\ldots\ldots i = i^{i+\frac{1}{2}}\,\epsilon^{-i}\sqrt{2\pi}$$

and therefore

$$\frac{n(n-1)\ldots\ldots(n-i+1)}{1.2\quad\ldots\ldots\quad i}=\frac{n^{n+\frac{1}{2}}}{\sqrt{2\pi i}\,(i+\frac{1}{2})(n-i)^{n}}$$

Hence for the case

$$i = n\frac{a}{a+b}$$

which, according to the preceding formulæ, gives T_i its greatest value, we have

$$T_i=\frac{1}{\sqrt{2\pi nef}}$$

where

$$e=\frac{a}{a+b}\text{ and }f=\frac{b}{a+b}$$

Thus, for example, let $n = 2\times10^{12}$;

$$e=\cdot2,\ f=\cdot8$$

we have

$$T_i=\frac{1}{800000\sqrt{\pi}}=\frac{1}{1418000}$$

This expresses the chance of there being 4×10^{11} molecules of oxygen in A, and 16×10^{11} in B. Just half this fraction expresses the probability that the molecules of nitrogen are distributed in exactly the same proportion between A and B, because the number of molecules of nitrogen is four times greater than of oxygen.

If n denote the molecules of one gas, and n' that of the molecules of another, the probability that each shall be distributed between A and B in the exact proportion of the volume is

$$\frac{1}{2\pi ef\sqrt{nn'}}$$

The value for the supposed case of oxygen and nitrogen is

$$\frac{1}{2\pi\times\cdot16\times4\times10^{12}}=\frac{1}{4021\times10^{9}}$$

which is the result stated at the conclusion of the text above.

WILLIAM THOMSON

LIVINGSTONE'S WORK IN AFRICA

THE daily papers have published some extracts from a letter of the late Dr. Livingstone to Mr. H. M. Stanley, which have been kindly furnished by the enterprising proprietor of the *New York Herald*; we reproduce here so much of the letter as bears on the geographical work done by Livingstone.

"The Chambezi was crossed long ago by the Portuguese, who have thus the merit of its discovery in modern times. The similarity of names led to its being put down in maps as 'Zambesi' (eastern branch) and I rather stupidly took the error as having some sort of authority. Hence my first crossing it was as fruitless as that of the Portuguese. It took me twenty-two months to eliminate this error.

"The Cazembe who was lately killed was the first who gave me a hint that Chambezi was one of a chain of rivers and lakes which probably forms the Nile; but he did it in rather a bantering style that led me to go back to the head waters again and see that it was not the mere 'chaff' of a mighty potentate. There is Omar Island in the middle of Bangueldo, with 183° of sea horizon around. The natives, slowly drawing the hand around, said—'That is Chambezi flowing round all this space and forming Bangweolo before it winds round that headland and changes its name to Luapula.' That was the moment of discovery and not the mere crossing of a small river.

"The late Cazembe I found sensible and friendly. His empire has succumbed before a very small force of Arab slaves and Banyamwezi. Pereira, the first Portuguese who visited the Cazembe eighty years ago, said that he had 30,000 trained soldiers, sacrificed twenty human victims every day, and that the streets of his capital were watered daily. I thought that my late friend had 30,0(00), diminished by two 00's, and sacrificed five or six pots of pombe daily; but this may have been only a court scandal—the streets of his village were not made. So I was reminded of the famous couplet about the Scotch roads:—

"'If you had seen these roads before they were made,
You would lift up your hands and bless General Wade.'

"I have been the unfortunate means of demolishing two empires in Portuguese geography—the Cazembes and that of the Emperor Monomotapa. I found the last about ten days above Tette. He had too few men to make the show Cazembe did, but I learnt from some decent motherly-looking women attached to his Court Zembere (?) that he had 100 wives. I have wondered ever since and have been nearly dumfoundered with the idea of what a nuisance a man with 100 wives in England would be. It is awful to contemplate, and might be chosen as a theme for a Young Men's Debating Society. I wish someone would visit Mtesa, or Uganda, without Bombay as an interpreter. He (Bombay) is by no means a sound author. The King of Dahomey suffered eclipse after a common-sense visit, and we seldom hear any more of his atrocities. The mightiest African potentate and the most dreadful cruelties told of Africans owe a vast deal to the teller.

"You and I passed the islet Kasenge, where African mothers were said to sell their infants for a loin-cloth each. This story was made to fit into another nice little story of 'a mother bear' that refused to leave her young. A child that cuts its upper front teeth before the under is dreaded as unlucky and likely to bring death into the family. It is called an Arab child, and the first Arab who passes is asked to take it. I never saw a case, nor have the Arabs I have asked seen one either, but they have heard of its occurrence. The Kasenge story is, therefore, exactly like that of the Frenchman who asserted that the English were so fond of hanging themselves in November you might see them swinging on trees along the road. He may have seen one; I never did. English and American mothers have been guilty of deserting infants; but who would turn up the whites of his eyes and say, as our mothers at Kasenge did, these people are no better than, or not so good as, she-bears?

"This lake, so far as I have seen it, is surrounded by

an extremely flat country, though all 4,000 ft. above the level of the sea. When first discovered I was without paper, but borrowed a little from an Arab, and sent a short account home. I had so much trouble from attendants that I took only the barest necessaries. Yet no sooner was the discovery announced at the coast than the official description was forthwith sent to the Bombay Government, that 'the lake is like Nyassa, Tanganyika, and the Albert Nyanza, overhung by high mountain slopes, which slope down to great plains, which, during the rainy season, become flooded, so that caravans march for days through water knee-deep seeking for higher ground on which to pass the night.'

"The only mountain slopes are ant-hills, some of them 20ft. high. They could scarcely be called high unless thought of as being built on the top of the 4,000 ft. These statements are equally opposed to the truth, as the Cazembe town is built on the banks of the Luapula.

"People having a crochet for map making traced every step of the Portuguese slaving expeditions to Cazembe, and built the village in latitude 8° 43′ South—that is, in deep water, near the north end of Lake Moero, and over 50 miles from Luapula. I found it in latitude 9° 37′ South, and on the banks of a lagoon or loch, having no connection with Luapula, which river, however, falls six or seven miles west of the village of Moero.

"Now it is very unpleasant for me to expose any of these misstatements and so appear contradictious. But what am I to do? I was consulted by Sir Roderick Murchison as to this present expedition, and recommended the writer of the above as a leader. Sir Roderick afterwards told me that the offer was declined unless a good salary and a good position to fall back upon were added, as Speke and Grant had, on their pay and commission. He then urged the leadership on myself as soon as the work on which I was engaged should be published. My good, kind-hearted friend added, in a sort of pathetic strain, 'You will be the real discoverer of the source of the Nile.' I don't wish to boast of my good deeds, but I need not forget them. . . ."

SOUNDINGS IN THE PACIFIC

RECENT explorations in the Pacific Ocean indicate that its bed is singularly level. The soundings of the U.S. steamer *Tuscarora*, Capt. George T. Belknap, between Cape Flattery and Oonalaska, were described in NATURE, vol. viii. p. 150. Upon the conclusion of that cruise, which included also soundings from Cape Flattery to San Francisco, a month was spent in the latter harbour, and on December 5 a survey was begun between that port and San Diego on the same coast, especially between depths of 100 and 1,500 fathoms. The latter depth or a greater one is reached precipitately along the entire coast of California, at distances of 20 to 70 miles from shore. Off the Golden Gate, in the latitude of San Francisco Bay, at a distance of 30 miles, there is 100 fathoms; at 55 miles' distance, there is a sudden descent from 400 fathoms to a depth of two miles; at 100 miles out, 2,548 fathoms failed to reach bottom.

Soundings between San Diego, California, and Honolulu, Sandwich Islands, show that this part of the Pacific is a basin with precipitous sides and a comparatively level bottom. The distance between these points, surveyed by the *Tuscarora*, is 2,240 miles. The work was accomplished between January 6 and February 3, favourable weather being experienced during almost the entire voyage.

In the first 100 miles west from San Diego, there appear to be two valleys and two peaks. The first valley is from 622 to 784 fathoms depth; the first peak 445 fathoms, the second valley 955 fathoms, the second peak 566 fathoms. Thence a precipitous fall takes place, giving in lat. 31° 43′ N., long. 119° 28′ W., at 115 miles from San Diego, a depth of 1,915 fathoms. After that there is a gentle slope with comparatively unimportant interruptions, at the rate of three feet to the mile, to the point of greatest depth, 3,054 fathoms, at a distance of about 400 miles east of Honolulu. The sharpest elevation is a rise about midway between the United States and the Sandwich Islands, in lat. 26° 30′ N., long. 127° 37′ W., the highest portion of which is 2,159 fathoms below the surface. At the next cast of the lead, the valley to the west of this elevation took 2,650 fathoms. The fall of the side of the basin east of Honolulu is even more remarkable than the descent off the American coast. Fifty miles from Honolulu, soundings gave 498 fathoms; at 40 miles farther east, in lat. 21° 43′ N., long. 156° 21′ W., the depth was 3,023 fathoms. Between the last-mentioned point and that of greatest depth a hill rises, on whose summit there are only 2,488 fathoms of water.

These soundings coincide very nearly with the determinations of the depth of the Pacific made on theoretical grounds by the United States Coast Survey in 1854. Those calculations were based on the movements of tidal waves occasioned by earthquakes in Asia. The wave that reached San Francisco had a length of 210 to 217 miles, an oscillation of 35 minutes, and a velocity of 6·0 to 6·2 miles per minute. This would give a depth of 2,200 to 2,500 fathoms. Similar data with regard to the wave that reached San Diego (having a length of 186 to 192 miles) were calculated as giving an average depth of 2,100 fathoms. The average depth of the present soundings is about 2,400 fathoms.

The bottom is generally a soft, yellowish-brown ooze, better suited in this respect, as well as in being more level, than the route surveyed toward Oonalaska, for a telegraphic cable. Other considerations of an economic character, such as prospects of connection with other telegraph lines, may also serve to overbalance the shortness of the more northern route, and there is much better prospect of fair weather for laying a cable and keeping it in repair in the lower latitudes.

Surface-temperatures rose from 59° F. near San Diego, to 74° F. near Honolulu; temperatures at 105 fathoms between the same places rose from 50° F. to 63° F. These, of course, indicate the equatorial current. At 300 fathoms the temperature was constant at 43° F. At bottom, the temperature was everywhere 35° F., except in a single instance where it was 1° colder. The uniformity of temperature below 1,600 fathoms was noticeable.

One wire has been used in all these soundings, which were made every 40 miles, and the apparatus still works excellently.

M. CHARLES SAINTE-CLAIRE DEVILLE'S WEATHER PROGNOSTICATIONS

THE prognostications delivered by M. Charles Sainte-Claire Deville, in his communication of March 2, before the French Institute, were wonderfully fulfilled, at least for Paris, the cold period having had its beginning on the 9th, and its end on the 13th, as was predicted. Public attention was all the more attracted because the cold was manifested by a heavy fall of snow, which was the first of the year. Having recently visited M. Ch. Sainte-Claire Deville, the learned physicist was kind enough to explain everything connected with his theories.

M. Ch. Sainte-Claire Deville has very often published similar prognostications which were always successful, but never in so striking a way. He has been a constant compiler of meteorological records for nearly twenty years; and being the Inspector-General of the French Meteorological Stations, as well as a member of the French Academy of Sciences, he has consequently at his command an immense number of trustworthy observations.

He has discovered that there is monthly a large thermometrical oscillation, which he calls dodecuple, from the

the Greek word δώδεκα, twelve; that dodecuple oscillation generally takes place in the second week of the month, but it is not equally marked every month, and besides it is not true to say that it is always exhibited by a depression of the mean temperature.

The November dodecuple oscillation decidedly exhibits a warming effect. February, March, and May have, on the contrary, a cooling effect. For centuries May and November were observed and noted as the "Saints de Glace" of the spring and Martinmas summer. But other oscillations, viz. February and March, which are generally very cold, were unnoticed.

The range of the oscillations, as well as their exact position *in time*, are different for different years, very probably because there is more than one single law in operation to produce them. Happily M. Charles Sainte-Claire Deville has discovered an indication which enables him to foresee which oscillations are to be the largest or the smallest.

Each dodecuple thermometrical oscillation is preceded by a similar dodecuple barometrical oscillation. The difference of time between both oscillations is variable, but the ordinary value is *five days*. Consequently, having noted a large barometrical dodecuple oscillation on March 2, he was certain that by the 8th the regular thermometrical dodecuple oscillation for March should appear very decidedly. The deviation of the thermometrical oscillation is uncertain, to the extent of four or five days.

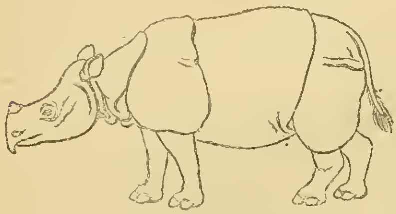
Everything is empirical in this wonderful method of announcing future oscillations of the thermometer by the careful observation of the barometer.

M. Charles Sainte-Claire Deville is of opinion that the phenomenon is owing to the presence of certain cosmical streams of meteoric bodies which may chance to be distributed in an irregular manner in the celestial space. These do not always keep just in the same place, owing to multifarious perturbations; they also vary in breadth, thickness, &c. All these assumptions are merely theoretical, but the existence of the dodecuple period in itself is based on pure observation, and cannot be questioned like the explanation offered for its origin.

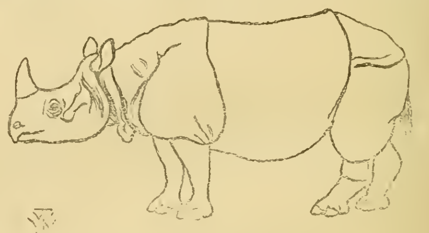
W. DE FONVIELLE

ON THE ARRANGEMENT OF THE SKIN-FOLDS IN THE ONE-HORNED RHINOCERI

IN the two accompanying woodcuts Mr. T. W. Wood has very carefully and accurately mapped out for us the manner in which the peculiar skin-folds, so conspicuous in both the Indian one-horned rhinoceri, are arranged over the surfaces of their bodies. The sketches were both taken from the specimens now living in the Zoological Gardens, the Indian animal (*Rhinoceros unicornis*) being a fully adult male, presented by Mr. A. Grote in 1864, and the Javan (*R. sondaicus*), the not quite full-grown example, of the same sex, just purchased. A fortnight ago (NATURE, vol. ix. p. 363) we mentioned some of the most important points by which the two species



R. sondaicus.



R. indicus.

are distinguished, laying stress on what is rendered so much more evident by the sketches we now give, namely, the peculiar manner in which the lateral shoulder-fold—which in the Indian species does not run up the middle line of the back, but is lost over the upper part of the scapula before it reaches the post-scapular transverse fold, as it is continued longitudinally backwards—in *Rhinoceros sondaicus* is carried perpendicularly upwards along the middle of the scapular shield, quite to the back, so as to cut off an extra, independent, saddle-shaped, small, median segment, which covers the nape of the neck. The peculiar notch in the post-scapular transverse fold, and the less extent of the longitudinal fold in the gluteal shield in the Javan species, is also very apparent. Another point which is well indicated is the difference in the shape of the upper lip in the two animals, it being short and blunt in *R. indicus*, whilst it is long, pointed, and semi-prehensile in *R. sondaicus*.

The head of the Javan rhinoceros is also proportionately smaller, whilst the skin-folds along the inferior surface of its neck are more symmetrical and numerous, being arranged so as to appear very like the surface of a coarse three-cord braid. Its skin, especially over the back, is covered with hair to a degree which would hardly have been expected, as in the Indian species there is but little hair to be seen. The ears are also fringed, much in the same way that they are in *Rhinoceros lasiotis* and *R. sumatranus*, the two Asiatic two-horned species.

The two sketches are made of one size to facilitate comparison, but it must be borne in mind that the Javan animal never reaches anything like the bulk of its Indian ally. It is also almost certain that its skin never becomes so coarsely tuberculated.

In rhinoceri kept in confinement there is nothing to be learnt from the shape or length of the horns, because that depends so much on the opportunities which their owners have had of rubbing them down. In the wild state the continual employment of the horn or horns in tossing and dividing comparatively yielding substances, such as loose earth and wood, causes them to become pointed, long, and polished, because they wear at the sides almost entirely. But in captivity the seasoned wood, iron, and stone of the cages only break off the tips and leave the sides comparatively unworn, or very unequally so; this is why museum specimens of horns are generally so very unlike those found on exhibited living animals.

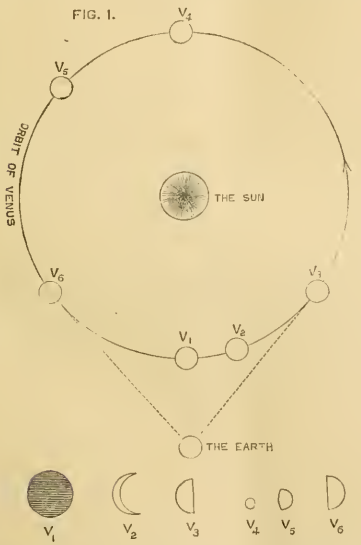
Those who noticed the illustrations we gave two months ago (NATURE, vol. ix. p. 227) of the huge *Brontotherium ingens* discovered by Prof. Marsh, will be struck, on looking at the Javan rhinoceros, with the general similarity in the proportions of the head in the two animals. The nose is undoubtedly different, but there is the same extreme shallowness of the frontal and interorbital region, combined with great zygomatic breadth. In Brontotherium the two expanded symmetrical nasal processes were probably covered with tough skin, like those on the face of the wart-hog, to replace in function the coreless but none the less well-developed horn of the rhinoceros.

THE COMING TRANSIT OF VENUS

I.

In days of old it was supposed that the earth held the central position of the solar system, and that moon, sun, and planets moved round it, each in its own orbit. The moon was supposed to be nearest to us, then came Venus, then Mercury, after that the sun, then Mars, Jupiter, and Saturn. We now know that of all these the moon is the only one which revolves round the earth, and that all planets go round the sun in the following order :—Mercury, Venus, the earth, Mars, Jupiter, Saturn. These are all the planets which were known to the ancients. Since Mercury and Venus were formerly supposed to be lower than the sun, and all the others higher, the name of *inferior planets* was given to the former, and *superior planets* to the others. These terms are still retained by astronomers, though the ideas that gave rise to these terms are long since exploded. Fig. 1 shows the phenomena exhibited by an inferior planet in the course of its journey round the sun. V is the planet Venus in the different parts of its orbit. E is the earth, which is shown in the figure always in one position, although of course it

FIG. 1.

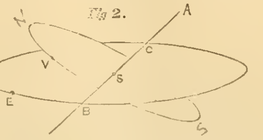


also describes an orbit round the sun. We are naturally led by a study of the diagram to three points of interest concerning the motions of an inferior planet.

The first is that the planet can never seem to be far distant from the sun. Venus moves round the sun in the direction shown by the arrow. The earth rotates in the same direction. We are supposed to be looking down upon the solar system from some point in the northern heavens. It will be noticed that when the planet leaves the point V_1 she will seem to recede from the sun more and more, until she reaches the position V_3. She can never be farther from the sun than this, and is then said to be at her greatest eastern elongation. She then approaches the direction in which the sun is seen, until she is lost in the brightness of his rays. During all this time she is seen best in the early morning before sunrise, setting before the sun. When Venus has passed this position her distance from the sun appears to an observer upon the earth to increase until she reaches V_6, her greatest western elongation, when she again begins to approach the sun.

The next point to be noticed is that she is sometimes a great deal closer to the earth than at other times; and when she is most near to the earth she appears to be larger. At her closest approach to the earth she is only about 26,000,000 of miles away; but when farthest off her distance is 158,000,000 of miles. Her apparent size is

Fig 2.

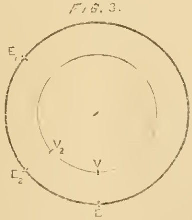


therefore much greater in the first case than in the second. These differences are shown at the lower part of Fig. 1.

The third point to be mentioned is that she exhibits phases just as the moon does. In any position that hemisphere alone is illuminated which is directed to the sun; so that in the position V_3, when we can only see one-half of that hemisphere, she will have the appearance of a half-moon. So in the position V_2 she has a crescent form, and at V_5 a gibbous form. The apparent size and shape of the planet in its different positions are shown in the lower part of Fig. 1.

The question now arises, what will happen when Venus is between us and the sun? In the first place, since her illuminated hemisphere is turned away from us, she will appear to be black; so that we shall have no chance of seeing her, unless she be seen as a black spot upon the bright surface of the sun. We would naturally expect that this should happen every time that the planet is at its least distance from us. A simple consideration shows that this need not be the case. The orbits of Venus and the earth do not lie in the same plane. In other words, we cannot represent accurately the paths of Venus and the earth by a drawing upon a sheet of paper. The orbit of Venus would have to be tilted up above the plane of the earth's orbit. Both of these planes pass through the sun, but they are inclined to each other at a certain small angle. This will be seen by a glance at Fig. 2, where V represents the orbit of Venus, E that of the earth. The line

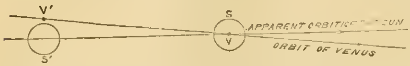
FIG. 3.



AB, which passes through the sun S, is called the line of nodes; and it is quite clear that in order to see Venus as a black spot upon the sun both the earth and Venus must lie approximately on this line of nodes. Now it generally happens that when Venus is at her least distance from the earth, these two planets occupy some such places as V and E, so that she seems to be above the sun; and, not being illuminated, she is invisible. Only twice in a century does she reach the node, so nearly at the same time as the earth, as to be seen as a black spot upon the sun. Such a phenomenon

is called a transit of Venus. If it happen that Venus seems to pass across the centre of the sun she takes about eight hours to complete the passage. The earth occupies the position A always in June, and the position B in December. If there be a transit of Venus when the earth is at B, Venus is said to be at the *descending* node, because then she is descending from the northern portion of her orbit to the southern. When Venus is at C she is at her *ascending* node.

FIG. 4

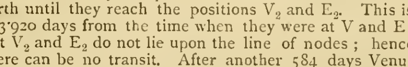


It has been said that there are, roughly speaking, two transits of Venus in a century. The following table shows all the transits of which we know anything :—

1631. Predicted by Kepler, but not observed.
1639. Predicted and observed by Horrox.
1761. Predicted by Halley ; observed by many.
1769. Observed generally.
1874.
1882.

It will be noticed that the transits occur in pairs, eight years apart ; the reason of this can easily be rendered clear. The earth takes 365·256 days to go round the sun ; Venus takes only 224·7 days. Suppose then that at any particular date Venus and the earth are at the node simultaneously, viz. at V and E, Fig. 3, a transit of Venus over the sun's diameter will be seen. When Venus has completed a revolution the earth will have moved away to E_1, and Venus will not overtake the earth until they reach the positions V_2 and E_2. This is 583·920 days from the time when they were at V and E ; but V_2 and E_2 do not lie upon the line of nodes ; hence there can be no transit. After another 584 days Venus will again be in conjunction with the sun, but still not on the line of nodes. But the fifth conjunction occurs after 2919·6 days ($5 \times 583·920$) ; and the earth completes eight revolutions in 2922·05 days. Thus it appears that, at this conjunction of Venus with the sun, the earth and Venus are very near to their old positions V and E. Hence they are almost on the line of nodes. In this case we can without difficulty examine the possibility of a transit. If we suppose the motion of the earth to be stopped, the apparent motions of the sun and Venus may be represented as in Fig. 4, where a portion of the orbit of Venus and of the ecliptic are shown near the nodes. When the sun and Venus are on the line of nodes simultaneously S represents the sun and V Venus. At the fifth conjunction the sun will not quite have reached S, but will be $2\frac{1}{2}$ days behind at S′ ; Venus will then be at V′. Now in this case there can be no transit visible, for here Venus is quite out of range of the sun. But if in the original transit the sun was a little past the node as at S (Fig. 5), then eight years after he will be at S′, and there will be

FIG. 5



another transit. It follows from this that there will be a pair of transits eight years apart, only when in the first one Venus does not pass close to the sun's centre. This equality of eight revolutions of the earth, with thirteen of Venus, is very interesting, because this fact was shown by the present Astronomer Royal to account for an inequality in the earth's motion due to the attracting influence of Venus. The result of a short calculation informs us that for positions of Venus and the earth near the line of nodes, Venus is at one conjunction 22′ 16″ distant from her position at the conjunction which occurred eight years previously,* this distance being measured at right angles to the ecliptic. Now the sun's diameter is 32′. This shows why, generally, there are two transits eight years apart.

The first prediction of a transit of Venus was made by Kepler,† and was calculated from his Rudolphine tables. In 1631, the year predicted, astronomers of Europe were eagerly on the watch for so rare a spectacle. But the calculation was in error, so that it took place when the sun was below the horizon in Europe, and was consequently invisible.

After this no astronomers seem to have interested themselves about the possibility of such an occurrence, with one exception. Jeremiah Horrox, a curate of the village of Hoole, near Liverpool, was much devoted to astronomical pursuits. ‡ He possessed some tables for calculating the places of the planets ; but his observations did not agree at all with them. He had, however, before discovering the faults of Lansberg's tables, calculated from them the future positions of the planets. This work, with corrections deduced from his own observations, led him to predict a transit of Venus, visible in England, for the year 1639. He acquainted his friend Crabtree, of Manchester, with the results of his calculation, and then prepared himself for the observation. He considered the best method to be the employment of a telescope to throw an image of the sun on a white sheet of paper in a darkened room. A circle was drawn, of about 6 inches diameter, upon the paper, to make the sun's image exactly fill the circle. A plumb-line would give him the direction of the vertical, and by marking successive positions of the planet on the sun's disc, he would be able to calculate many of the elements of Venus. Such an observation is of course peculiarly well suited for determining the diameter of the planet, the inclination of its orbit, the position of the node, and the true time of passing this node. His calculations showed that the transit ought to commence on the afternoon of November 24 (old style) ; but to guard against disappointment, and because of discrepancies in various tables, he kept a watch from the 23rd. On returning from some clerical duties on the 24th (Sunday) he was gratified by beholding a black spot on the sheet of paper, which indicated the presence of Venus on the sun's disc. He made three observations before sunset and has left us a drawing to illustrate the observations. §

It is curious to find an astronomer supporting the opinions of the astrologers ; but in his treatise we find that the chance of a clouded atmosphere caused him much anxiety, for Jupiter and Mercury were in conjunction with the sun almost at the same time as Venus. This seemed to him to forbode great severity of weather. He adds, "Mercury, whose conjunction with the sun is invariably attended with storm and tempest, was especially to be feared. In this apprehension I coincide with the opinion of the astrologers, because it is confirmed by experience ; but in other respects I cannot help despising their more than puerile vanities." But we must not laugh at Horrox for his opinion. In our own day there is a considerable number of diligent astronomers who believe that the cyclones in the Indian Ocean, certain other winds, the growth of vines, and various other

* For at the fifth conjunction the earth is 2·45 days distant from her place at the original conjunction. This is equivalent to 2° 24′ 59″, when viewed from the sun, from which subtract 2′ 44″ (= the retrogression of the node of Venus in eight years), and we have 2° 22′ 15″ = the angular distance of the earth from its corrected original position, as seen from the sun. The ratio of this to the angular distance of Venus from her original position as seen from the earth $= \frac{\text{dist. of Venus from earth}}{\text{dist. of earth from sun}} = \frac{277}{723}$. Multiplying 2° 22′ 15″ by 723, and dividing by 277, we have 6° 11′ 17″. Multiplying this by ·06 = tan 3° 23′ 31″, which is the inclination of the orbit of Venus, we have 22′ 16″ = the latitude of Venus at the fifth conjunction.

† 'Admonitiuncula ad Curiosos rerum Cœlestium," Leipsic, 1626.

‡ See NATURE, vol. viii. p. 113,

§ Venus in Sole Visa.

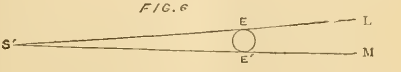
phenomena, are in part regulated by the positions of Venus and Jupiter with respect to the sun.*

Mr. Horrox's observations have been of great value in perfecting the tables of Venus. He was further led by a kind of analogy, much in vogue at the time, to deduce from his observations a value of the sun's distance from the earth. It will readily be understood that if we could find out what size, in angular measure, the earth would seem to have if viewed from the sun, we should have a means of determining how much greater the distance from the earth to the sun is than the diameter of the earth. For, suppose S (Fig. 6) to be the position of an observer placed upon the sun, S L, S M the directions in which he must look to see the opposite sides of the earth, so that the inclination of these lines is known. All we have to do now is to draw a circle of any size and move it about between the lines S L, S M, until it just fills the interval, as at E E′. If now we measure with a ruler how much greater S E is than E E′ we shall know the distance from the earth to the sun, the earth's diameter being taken as the unit of measurement; and if we multiply this by the diameter of the earth measured in miles we shall know the distance from the earth to the sun, in miles. All that we require to know is the size of the angle E S E′. Horrox estimated the probable value of this angle in the following manner. From the observations of Tycho Brahé it appeared that during the transit of Venus the apparent diameter of the planet would be 12′ 18″; while Lansberg found 12′ 21″; and Kepler 6′ 51″. Horrox found from his measurements that it was only 1′ 16″. The error of ordinary observations arises from the apparent enlargement of the planet's disc through irradiation. Gassendi had in the same manner, during the transit of Mercury in 1631, reduced the apparent diameter of Mercury to scarcely 20″. From these data it can be found that the apparent diameters of Venus and Mercury as seen from the sun would be 21″ and 34″ respectively. Proceeding to the other planets he arrived at the general conclusion that each of them would, if viewed from the sun, have an apparent diameter of about 28″. Applying this to the case of the earth, he showed that the distance of the earth from the sun must be 7,500 diameters of the earth (it may be well here to state that the latest measurements show the apparent diameter of the earth as viewed from the sun to be about 18″, and the distance = 11,400 diameters). This analogy by Horrox gave a much closer approach to the truth than any previous conjectures.

Before taking leave of Horrox, we must say a few words to his memory. He died at the early age of 23. During his short career he showed a remarkable aptitude for the acquisition of knowledge, and for the striking out of new ideas. He lived at a time when the scientific spirit of the age was leading up to the theory of gravitation, and many passages in his writings show that he had even then grasped the grand idea of the theory, and that he was well fitted to become its constructor and its expounder. His researches on the lunar and planetary theories indicate the magnitude of his talents.

We have already mentioned some of the uses to which careful observations of a transit of Venus may be applied; viz. the correction of the elements of the planet's orbit. But the observation also leads us to a knowledge of the distance of the sun from the earth, and in a manner much more direct and logical than that employed by Horrox. There is an opinion very prevalent that a transit of Venus affords the best means of determining this distance. So

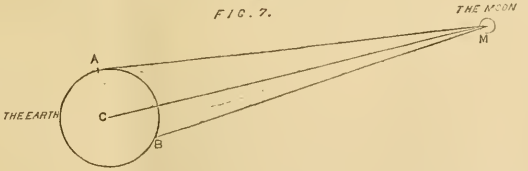
FIG. 6



far as our present knowledge goes we are hardly justified in such a statement until after the observations that shall be made in the present year.

Before entering upon the method by which we measure the sun's distance, let us devote a few lines to explaining what is meant by the word *parallax*, which is continually employed in such discussions. Let a man stand in a street exactly north of a lamp-post. The lamp-post will seem to be south of him. Now let him cross over to the other side of the street. The lamp-post will now be in some other direction, such as south-west. This movement of the direction of the lamp-post is the effect of parallax. Now let us suppose, by a stretch of imagination, that a man observes the moon from the centre of the earth. He will see it in the direction C M (Fig. 7). If now he goes to A he will see it in the direction A M. The angle A M C through which the moon appears to have been moved is the parallax of the moon as observed from A.

FIG. 7.



It will be noticed that the parallax is an error introduced into the observed position of the moon, and which must be allowed for if we wish to get the position as seen from C. Moreover, the parallax at B is different from what it is at A. But at no point on the surface of the earth can the parallax be greater than at A. And if we know the parallax of the moon at A, we can deduce that at B from a knowledge of the relative positions of A, B, and C. Hence it is useful to have a distinct name for the parallax at A. Now it will be noticed that a line drawn from C to A is the vertical line at A; hence the moon M will appear to be on the horizon to an observer at A; and hence the moon has its greatest parallax when on the horizon. For this reason the parallax at A is called the moon's *horizontal parallax*. Further, since the equatorial diameter of the earth is greater than the polar, the parallax will be greater, when the moon is on the horizon, to an observer at the equator than to an observer at one of the poles. Hence the greatest parallax we can have occurs when the moon is on the horizon and the observer is at the equator; this value of the parallax is the *equatorial horizontal parallax*. In the same way the sun has an equatorial horizontal parallax, and if we knew its value we could find out the sun's distance from the earth as explained above (Fig. 6).

GEORGE FORBES

(*To be continued.*)

* See the researches of Messrs. De la Rue, Stewart, and Loewy on the connection of sun-spot frequency with planetary positions, "Phil. Trans."; also the writings of Mr. Meldrum, Mr. E. J. Stone, Prof. Balfour Stewart, M. Poey, and others, on the connection between terrestrial phenomena and sun-spot frequency.

THE "CHALLENGER" EXPEDITION

III.

St. Vincent, Cape de Verde Islands

St. Vincent, one of the Cape de Verde Islands, noted in the old gazeteers for its wood, water, wild goats, turtles, and saltpetre, was visited by the *Challenger* in July and August last. From a record of this visit we gather the following particulars about the island itself and of the plants growing there. The island is small, not more than twelve miles by six, comparatively flat in the centre, but surrounded by higher land. This range of high land is divided by a series of deep valleys, forming ridges which are again divided into transverse valleys. Most of the hills are from 700 to 1,200 ft. high, but one in the south is over 2,200 ft. high. St. Vincent is sometimes visited by long periods of drought, extending occasionally to a year's duration, during which time the whole island has a parched, sterile appearance. The most abundant plant in the island is *Lavandula rotundifolia* Bth., which forms small thick bushes; there is also on the summits of the higher hills *Euphorbia tuckeyana*, Steud., and on the sandy plains as seen from the vessel in Porto Grande, reaching inland from the shore, were dense masses of bushes of *Tamarix gallica.* In one spot, springing up from amongst these bushes, was the well-known tamarind tree (*Tamarindus indica* L.), so valuable both in the East and West Indies, for the sake of the agreeable acid pulp contained in the pod, which when preserved in sugar forms "Tamarinds" of commerce. Side by side with the tamarind grew *Acacia albida* Del., and *Terminalia catappa* L., the first being one of the many spiny acacias found on the African continent, where it forms a large straggling branching tree, with straight, stout spines, sometimes ¾ in. long. The *Terminalia* is a native of India, but has been found in Upper Guinea, though probably not indigenous. The seeds are almond-shaped, white, and of an agreeable taste. In the plains *Tribulus cistoides* L., a spreading prostrate or decumbent plant, occurs in great abundance, as also a small grass. Nearly all the vegetation, however, had a shrivelled, dried-up appearance, with the exception of the lavender, upon which a few fresh green leaves were to be seen. The effect of rain in changing the aspect of vegetation on this island is said to be almost instantaneous, not only in bringing out the young foliage of perennial plants, but also in causing a thick carpet of seedlings to spring up. Though the hill slopes and the lower parts of the valleys are in some parts of the island covered with a thick grass, the drought causes it to become so dry that goats and cattle frequently die from sheer starvation.

On the Green Mountain, at an altitude of about 200 ft. above the level of the sea, the gardens contained pumpkins, sugar-cane, a small kind of date-palm, and maize; cotton bushes also grew in the neighbourhood. At another 500 ft. there were Euphorbias and the woody Composites. At 1,000 ft. there were *Echium stenosiphon* Webb, in flower; and at 1,300 ft. occurred patches of moss and marchantia, while at 1,700 ft. *Statice jovi-barba* Webb was abundant. The *Lavandula rotundifolia*, which is found at the very top of the mountain, has here a very different aspect from that before described, inasmuch as it is green and vigorous-looking. In the south-west of the island, at a height of 900 ft., was discovered a single plant of *Sarcostemma daltoni* Dcne, which grows on the cliffs at St. Jago, almost down to the sea. On the top of the Green Mountain the land is much cultivated with potatoes, tomatoes, pumpkins, maize, and similar plants. The position is so favourable to the growth of the tomato that it appears to have run wild. The origin of many of the introduced weeds which grow on the mountain is no doubt traceable to the imported seeds of the vegetables just mentioned.

At an elevation of about 2,000 ft. was a group of agaves planted in the form of a double circle; many of them had flowering spikes about 10 ft. high. The marked differences of aspect caused respectively by the trade-winds and the sun, at altitudes suitable for plant growth, are points of much interest, illustrations of which may be had in the fact that *Aizoon canariense* L., which grows on the windward and shady side of Bird Rock, nearly down to the sea-level, does not commence till 700 feet or 800 feet on the leeward sides of the main island; the Euphorbias and woody Composites are found at about the same elevation, while on the other side they reach nearly down to the sea. On the windward slopes of the mountains, on the southern side of the island, the vegetation commences at a higher elevation, being kept back by the wind becoming heated and dry from its passage across the hot central plain.

Sinapidendron vogelii Webb, a cruciferous undershrub, with yellow flowers, grows on the cliffs on the weather side of the island; and *Samolus valerandi* L., known to us as the brookweed or water pimpernel, an erect plant, from 8 in. to 10 in. high, growing in marshy places or near springs, was also seen, but only in a single isolated patch near a small stream. This plant is remarkable for its very wide geographical range, being found in almost every country where the soil is wet and gravelly, and though seen only in this one spot in St. Vincent, it grows abundantly in St. Jago by the stream in St. Domingo Valley.

As seen from the sea, the rocks of St. Vincent present a singular appearance, owing to the presence of a thick incrustation at water-mark of masses of calcareous algæ, which either follow the forms of the rocks, or occur in rounded masses, their delicate tints of white, light pink, or cream colour, considerably heightening the effect. These incrustations are frequently bored by *Lithodomus candigerus* and other molluscs, and small sponges and Bryozoa occupy the cavities between them and the rocks.

St. Paul's Rocks

The isolated rocks known as St. Paul's Rocks lie to the north of the equator about 1°, and in longitude 29° 15′ W., nearly midway between the South American and African coasts. They are in truth mere rocks, not more than a quarter of a mile long, and rising to a height of from 50 to 60 ft. above the sea. They are described by travellers as being quite bare of land-vegetation even to the exclusion of lichens, the only vegetation in fact being numerous species of algæ.

From an examination made of the rocks during the two days' stay of the *Challenger*, it seems that the species of algæ are by no means numerous, fourteen species being all that were found; so powerful indeed is the wash of the waves that it seems to be too much even for these marine plants to retain their positions. The water also deepens very rapidly round the rocks, so that it is not likely many species would be found there.

A similar incrustation of calcareous algæ is seen upon the rocks as at St. Vincent. It here forms a deep pinkish white band at tide mark, and is riddled through and through by a small annelid. In some places the colour of the incrustation is white, and above this is a dark red-coloured algæ, covering the rocks for several feet. At the bottom of the small bay formed by the circlet of rocks and extending out in the sea to a depth of twenty fathoms, is a thick growth of a green-coloured sea-weed (*Caulerpa clavifera* Ag.), together with another species of smaller growth. The former is loosened from the bottom by the action of the waves, and is gathered up by the noddies (*Sterna stolida*) to build their nests.

A few diatoms and oscillatoriæ occur in stagnant pools, among them being *Navicula didyma*, *Rhabdonema adriaticum* and *Biddulphia pulchella.* A careful examination of the guano found in the hollows of the rocks showed that no diatoms were present, but fossil fragments of incrus-

tation formed of a kind of nullipore, combined with pebbles and broken shells, occur in the singular veins of conglomerate traversing the rock.

NOTES

WE are glad to hear that Government have consented, though tardily, to give effect to the wishes of the country, by offering to defray the expenses of the funeral of Dr. Livingstone in Westminster Abbey. The *Times* states that a merchant in the city of London, in view of the inability of Dr. Livingstone's family to bear the expense of the ceremonial, had already volunteered to be at the charges of this melancholy tribute of respect, but it obviously would have been unbecoming the dignity of the nation which has been honoured by the achievements of the illustrious traveller for the last honours to have been rendered him at the cost of any private person. The Southampton Town Council has resolved to receive, with fitting honours, the remains of Dr. Livingstone, which are expected to arrive at that port very shortly.

AT an influential meeting held at Edinburgh on Monday, it was resolved to extend on a large scale the University buildings and to remodel those already existing, so as to suit them to modern requirements. We are glad to notice that the importance of Science in University teaching was insisted on at the meeting, and we hope that in the extended and remodelled University scientific teaching and research will be accorded a prominent place. Of the 100,000*l.* required, 55,000*l.* have been already subscribed At Dundee, on the same evening, Dr. Lyon Playfair, speaking on the same subject, urged the importance of placing the Edinburgh University in a position in which it would be able to teach, in a thoroughly practical manner, the sciences and the professions resting upon them. He dwelt on the great importance of scientific education, and said that any nation which bestowed more science and skill on any one of their manufactures than we did must inevitably beat us in the race. He pointed to the advantages which Germany had derived from bestowing special attention to scientific instruction, and said that in Manchester we now saw the remarkable spectacle of an inland trading town of England in which Germany occupied much of the field of industry.

THE French Government have only done an act of justice in conferring a pension of 12,000 francs upon M. Pasteur in consideration of his services to science and industry.

COLONEL STUART WORTLEY has been appointed by the Commissioners of Patents to the Curatorship of the Patent Museum at South Kensington, vacant by the death of Sir Francis Pettit Smith.

SIGNOR AUGUSTO RIGHI has been appointed Professor of Natural Philosophy in the Instituto Technica Reale of Bologna.

THE Council of the Society of Arts has decided to offer a prize, consisting of a gold medal or 20 guineas, for the best essay "On the Cultivation and Manufacture of Indian Teas."

A MEETING of the local general committee of the British Association was held in the rooms of the Chamber of Commerce Bradford Exchange, on March 31, to receive a report as to the reception fund. It appeared that the total receipts were 3,248*l.* 16*s.* 8*d.*, and the expenditure 3,097*l.* 7*s.* 2*d.*, leaving a balance of 155*l.* 9*s.* 6*d.* in the bank, subject to the expenses connected with the winding up of the committee's duties. It was agreed that the balance remain in the hands of the local executive committee until all expenses are paid, and that the amount which may remain be given to the Bradford Philosophical Society, an institution having an object kindred to tha of the British Association.

M. LEVERRIER has been appointed president of the section of Science at the meeting of the Delegates of Learned Societies, which will be held at Sorbonne.

FROM the sixth quarterly report on the Sub-Wealden Exploration we learn that during the last two months a depth of 359 ft. has been bored, making a total of 671 ft. The borings are still in the Kimmeridge clay. In this deposit indications of petroleum have been noticed, and at depths of from 600 ft. to 650 ft. it was particularly observable. Occasional veins of carbonate of lime have been met with crossing the cores obliquely, but the report states that all the beds yet passed through are horizontal. One of the most important results of the exploration has been the discovery of gypsum and other beds which are likely to prove commercially productive. Attached to the report is a list of the fossils which have been found. The committee report that they have sufficient funds to continue the work to a depth of 1,000 ft., and should it be deemed desirable to go beyond that depth, a conference will be held to consider the question before soliciting further contributions. The present balance in hand is 576*l.* 4*s.* 4*d.*

IT is said MM. Croce Spinelli and Sivel will be awarded a prize for their last aeronautical ascent, in which they took with them oxygenised air.

ANOTHER aeronautical ascent took place on Thursday week from Lavillette gasworks in a new balloon called "Michel le Brave," which is to be sent to Roumania. The measurement is 1,500 cubic metres. It was sent up with six persons and descended at Vic-sur-Aisne in a regular storm; large trees were uprooted, but no bodily harm was received by the balloonists. It is intended to have several other ascents next spring.

THE greatest alarm has been caused in North Carolina and Tennessee by the appearance of what seems to be volcanic phenomena in the former of these states. The scene of the reported disturbance is Bald Mountain, in the south-western part of M'Dowell County. Rumblings were heard during several days, apparently coming from the interior of the mountain, and one letter, dated March 20, states that near the summit of the peak an area of nearly an acre was agitated by subterranean upheavals, and from which smoke and vapour issued. The people of the surrounding district are reported as being in the greatest consternation, ceasing from work and living in common, and evidently quite expecting that the final catastrophe is impending.

SEISMIC commotions of some magnitude have been felt in Algeria, at Algiers, and surrounding places. The centre of commotion seems to have been somewhere in the vicinity of Cherchel, where the barracks have suffered much. The first shock was felt on March 28 at 11.10 A.M.

AN Alpine club has been established in Paris under the presidency of M. de Billy. The rules will be similar to those of English, Swiss, Italian, and Austrian Alpine clubs. It is intended to issue a periodical containing the papers read before the Association. More than 100 members have been enrolled.

THE sittings of the Bureau des Longitudes are now being held at the Collége de France.

THE Mexican Axolotls, which have for some time been exhibited in one of the handsome vases in the entrance-hall of the Brighton Aquarium, spawned about a month ago. As the parents showed some disposition to devour their eggs, the latter were removed to one of the troughs of the salmon-hatching apparatus, where the young axolotls may now be seen, having just been hatched after a period of 29 days in the egg.

A SUPPLEMENTARY credit of 4,000*l*. has been voted by the Versailles National Assembly for paying a part of the expenses incurred by the observation of the Transit of Venus. Six members belonging to the ultra-clerical party have given a negative vote on a division. It is said they are not believers in the Copernican theory, and have no faith in the astronomical observations.

THE Rev Henry Moule, after a series of experiments extending over twenty years, has devised a process of manufacturing an illuminating gas from Kimmeridge clay.

THE educational means of Harvard University have recently been increased by the addition of an institution which will make that University one of the most complete in the United States. This Institution is known as the "Bussey Institution," after Mr. Benjamin Bussey of Roxbury, Mass., who about thirty years ago left to the University a magnificent sum of money and a small estate for the purpose of promoting the scientific study of agriculture and horticulture. The money was allowed to accumulate for many years, and has since been increased by 100,000 dollars left by Mr. James Arnold, Merchant, of New Bedford. The estate has been to some extent laid out for the purpose intended, and several suitable buildings, including a laboratory, have been erected, and the Harvard authorities have devised a course of instruction and investigation on a broad and thoroughly scientific basis. The appointments already made include:—An instructor in Farming, a professor of Agricultural Chemistry, a professor of Horticulture, a professor of Applied Zoology, an instructor in Entomology, a director of the Arnold Arboretum, and a librarian and curator of Collections. The institution is intended both for instruction and investigation, though we are glad to see that students' fees are not necessary to the support of the institution. The permanent funds provided by Mr. Bussey will enable the President and Fellows to maintain the Institution as a scientific station, like the Astronomical Observatory or the Museum of Comparative Zoology at Harvard College, until the time shall come when there shall be a demand for its privileges as a school. The experiments and investigations made at the Bussey Institution will be published from time to time in a Bulletin, the first number of which is before us. It contains four papers by F. H. Storer, professor of Agricultural Chemistry in Harvard University, one containing analyses of some commercial fertilisers, another of American "shorts" and "middlings," a third On the Agricultural Value of the Ashes of Anthracite, and a fourth containing a Record of Trials of various Fertilisers on the ground of the Bussey Institution. The only other paper is a useful one by Dr. Slade, professor of Applied Zoology, On the Humane Destruction of Animals.

THE French Society of Geography, we learn from *La Nature*, has just received news of a French expedition which has been exploring Terra del Fuego. On December 7, last year, the expedition landed on the coast of that island, and proceeded into the interior. The explorers found a large lake of 25 kilomètres in circumference, surrounded by luxuriant vegetation, and literally covered by an army of wild fowl, among which the most abundant were ducks and geese. These regions are inhabited by rude but hospitable tribes; the women especially are very affable and obliging. One of them, in exchange for some pieces of sugar and common handkerchiefs, gave the leader of the expedition an object to which she attached an immense value, and which she preserved as a relic,—the lid of a sardine box.

WITH a view of properly exhibiting the geological and metallurgical resources of America at the forthcoming exposition at Philadelphia, an association has been organised, embracing such names as those of Prof. Leslie, Prof. Genth, Prof. Raymond, Prof. Wyman, Prof. T. Sterry Hunt, George H. Cook, and others, to whom is to be intrusted by the Board of Centennial Commissioners the duty of collecting whatever will best answer the purpose in question.

THE Paris Jardin d'Acclimatation has succeeded in "breaking-in," some zebras so far as to induce them quietly to draw a carriage, and one permits children to ride round the gardens on its back.

DR. HAYDEN, the head of the Geological and Geographical Survey of the U.S. Territories, has commenced the publication of a bulletin to communicate such announcements of new facts made by any member of his party as it is desirable to bring promptly to the notice of the scientific community in advance of their publication in his reports. The first number of this Bulletin, bearing date January 21, is occupied by a list of the members and collaborators of the survey for 1873, and a list of the publications, from which we learn that six volumes of the reports have appeared from 1867 to 1873, and that seven volumes of miscellaneous publications will be published in octavo form, the most elaborate being the hand-book of the Ornithology of the North-western Territories, by Dr. Coues. Several quarto volumes will also be sent out, of which there have been actually published one by Prof. Leidy, on the extinct vertebrata of the Western formations, and one on the Acrididæ of North America, by Prof. Cyrus Thomas. This quarto series, it is expected, will include ten volumes, among them memoirs on the vertebrata of the cretaceous and Tertiary formations, by Prof. Cope; one each, on the fossil plants, by Prof. Newberry and Prof. Lesquereux; on the fossil invertebrates, by Prof. Meek; and the volume on general geology, by Prof. Hayden. Thirteen maps have been published for the survey, those of the Yellowstone region being especially valuable. The body of the bulletin is occupied by a report on the stratigraphy and Pliocene vertebrate palæontology of Northern Colorado, by Prof. Cope, in which he presents the parallelism of the formations recently investigated by him with those earlier known and in other parts of the West. He concludes that, although these formations have generally been considered as Tertiary, the geological evidence shows them to be strictly mesozoic, as in the great lignite formations on the Missouri River. During the past season twenty-one new species of vertebrates were obtained in the Pliocene sandstone at the head of the watershed between the South Platte River and the Lodge-pole Creek.

THE *Belgique Horticole*, for February, publishes a complete list of botanical gardens throughout the world, with the names of their curators and of the professors of botany at the different towns.

THE Science and Art Department has issued a catalogue of apparatus for instruction in geology, mineralogy, animal physiology, elementary botany, general biology, principles of mining, and physical geography.

THE *Brisbane Courier* of December 30, 1873, publishes the following official telegram from Mr. Walter Hill, the Government botanist, dated from Cardwell on the 27th and received by the Queensland Secretary for Lands:—"Since November 20 we have examined the banks of the Mulgrave, Russell, Mossman, Daintree, and Hull Rivers, and have been more or less successful in finding suitable land for sugar and other tropical and semi-tropical productions. The ascent of the summit of Bellenden Kerr was successfully made by Johnstone, Hill, and eight troopers. At 2,500 ft. in height we observed an undescribed tree with crimson flowers, which excels the *Poinciana regia*, *Colvillia racemosa*, *Lagersstroma regia*, and the *Jacaranda mimosifolia*. At 4,400 ft. a tree-fern, which will excel in grandeur all others of the Alboreous class. A palm-tree at the same height which will rival any of the British-Indian species in gracefulness. On

the banks of the Daintree we saw a palm-tree cocoa, which far exceeds the unique specimens in the garden of the same genera from Brazil in grandeur and gracefulness. While cutting a given line on the banks of the river Johnstone for the purpose of examining the land, an enormous fig-tree stood in the way, far exceeding in stoutness and grandeur the renowned forest giants of California and Victoria. Three feet from the ground it measured 150 ft. in circum erence; at 55 ft., where it sent forth giant branches, the stem was nearly 80 ft. in circumference. The River Johnstone, within a limited distance of the coast, offers the first and best inducements to sugar cultivation."

WE are glad to observe signs of life in Dundee, says the *Scottish Naturalist.* That town, long noted for its commercial enterprise, has had nearly an equal, but not enviable, celebrity for its poverty and deadness in regard to the study of natural science. But now we trust that that reproach will soon be wiped away, and that the members of the recently founded Dundee Naturalists' Society, a copy of whose constitution is before us, will do good work, and show their fellow-citizens that there are other and more valuable *dona Dei* in the fields, woods, and mountains of the interesting county of Forfar, than that wealth for which the inhabitants of the town of the *donum Dei* are deservedly remarkable. The Society has already upwards of forty members, which number will probably soon be considerably increased. We recommend to the Society the formation of a good local museum of the natural productions of Forfarshire.

IN the forty-first volume of the *Journal of the Asiatic Society of Bengal*, Mr. G. E. Dobson has drawn attention to a particularly interesting feature in the osteology of the Rhinolophine Bats. In the genera *Phyllorhina*, *Triænops* and *Cœlops*, he finds that in the innominate bone the ilium sends forward a process from its upper part, which meets and anchyloses with an extension of the ileo-pectineal spine to form a second foramen above that around which the obturator muscles arise. This peculiarity has not been observed in any other mammal.

THE additions to the Zoological Society's Gardens during the last week include a St. John's Monkey (*Macacus sancti-johannis*) from China, and a Java-Chevrotain (*Tragulus javanicus*) presented by Captain Nutsford; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. W. Webster; three Passenger Pigeons (*Ectopistes migratorius*) from North America, purchased; an Egyptian Monitor (*Monitor niloticus*) six feet long; and a Tuberculated Lizard (*Iguana tuberculata*) from the West Indies, deposited.

SCIENTIFIC SERIALS

American Journal of Science and Arts, March.—This number commences with an interesting paper, by Prof. Leconte, On the Great Lava Flood of the West, and on the Structure and Age of the Cascade Mountains. The flood, commencing in Middle California in separate streams, became in Northern Oregon and Washington absolutely universal; the whole country, mountain and valley, being buried several thousand feet. Its extent cannot be less than 200,000 to 300,000 square miles; its average thickness is probably 2,000 ft., and extreme thickness 3,700 ft. From the structure of the Cascade Range (which extended throughout the entire region of the flood) and palæontological evidence, the author thinks the flood began to occur during or after the Miocene; and the process of flooding probably continued, by successive fissure-flows of lava, chiefly in the Cascade and Blue Mountain Ranges, until the Post-Tertiary; the liquid matter having been squeezed out by horizontal and vertical pressure, while water, percolating through the hot mass, generated volcanoes that continued the up-building process.—Dr. Blake of San Francisco has a paper On the Connection between Isomorphism, Molecular Weight, and Physiological Action. One of the conclusions arrived at is, that among compounds of the more purely metallic elements, the quantity of substances in the same isomorphous group required to produce analogous changes in living matter, is less as the atomic weight of the electro-positive element increases.—Mr. Carey Lea describes some experiments made to determine whether it is a general law that when a metallic compound reducible by light is placed in contact with an oxidisable body (or one capable of uniting with Cl, Br, or I, as the case may be), the capacity of reduction of the compound by any particular part of the spectrum is influenced by the *colour* of the body placed in contact with it. But he did not succeed in thus generalising Vogel's results; which, however, he does not regard as contradicted or disproved.—Some experiments by Prof. Wright on the oxidation of alcohol and ether by ozone, seem to indicate that the vinegar process might be materially accelerated by passing ozonised air through the apparatus.—Prof. Marsh communicates a notice (bearing on the genealogy of the modern horse) of new equine mammals from the Tertiary formation; and we further note papers On Recent Dredging Operations in the Gulf of St. Lawrence (Mr. Whiteaves); On Fossils figured in the Illinois State Geological Report (Mr. Meek); On Dissociation of certain Compounds at very low Temperatures (Mr. Leeds), &c.

Der Naturforscher, February.—We may first note, in this number, an account of some valuable researches by MM. Pettenkofer and Voit, as to the significance of the carbohydrates in nutrition. The authors conclude that carbohydrates, in the animal system, always pass entirely into carbonic acid and water, and do not produce fat; but they save (*ersparen*) the fat produced from albumen, and this in proportion to the quantities of the albumen-fat and the carbohydrate. There is also, in the biological department, a succinct statement of Prof. Haeckel's "Gastraea" theory.—In geology, some observations by M. G. Laube appear to indicate that the transport of *débris* and stones by ice in East and West Greenland is by no means a common thing; and a note by M. Albert Heim describes and explains the formation of certain huge cauldron-like cavities in solid rock in the Gletschergarten at Lucerne.—From an examination of plant-remains found in amber, Prof. Caspary has inferred that Prussia, in the Amber period, must have been much warmer than now; certain Arctic Ericaceæ, supposed to be of the period, probably flourished on lofty mountains.—M. Merget's recent observations on thermo-diffusion of gas in leaves, and those of M. Reinke on the function of leaf-teeth, are also given; while MM. Fliche and Grandeau study the relation between chemical composition of the ground and vegetation of *Pinus pinaster.* This plant, while a flint-loving species, yet absorbs a considerable quantity of lime; and in soils with much lime, the increased absorption of this salt is accompanied with a decrease in the other ash constituents, especially potash (this being probably the cause of the bad condition of the tree in such soil).—In the department of physics, we have several notes from English sources: On the Elements present in the Sun (Lockyer); On the Affinities of the Magnetic Metals, and On Molecular Phenomena in Glowing Iron (Barrett); On Propagation of Sound in Fog (Reynolds), &c. And in chemistry, there is a note by M. Thomsen, treating of the influence of temperature on chemical phenomena of heat; also a popular summary of M. Ebermayer's researches as to the presence of ozone in the air.—Astronomy is represented by papers on the star shower of November last, and on the direction of the large axes of cometary orbits.

Bulletin de l'Académie Royale de Belgique. No 1, 1874.—In this number M. de Wilde makes some contributions to the theory of bleaching of vegetable fibres which contain incrusting and other matters. He considers that there is substitution of chlorine for hydrogen in the alkaline liquid, which has served to dissolve the incrusting matter, and that chlorine acts, besides, in decomposition of the water, formation of hydrochloric acid, and fixation of oxygen in the organic matter.—The same author communicates notes on the preparation of acetylene, the action of hydrogen on acetylene and ethylene under the influence of platinum black, and the action of the electric effluvia on some gases and gas-mixtures. In the last he confirms MM. Thenard's observations; and acetylene, he finds, is condensed by the effluvia into a liquid which solidifies rapidly, becoming yellow; the solid detonates under the action of heat. Sulphurous anhydride and oxygen combine directly to form sulphuric anhydride.—Continuing his researches on glyceric derivatives, M. Henry describes an octobromide obtained by action of bromine on tetrabromide of dipropargyle; and a paper by M. Spring, describing new syntheses of hyposulphurous acid and of trithionic acid, is of theoretical importance as showing the relations between the sulphates and hyposulphates, and between the latter and trithionates.—

M. Gosselet furnishes a detailed account of the southern band of Devonian limestones in the district Entre-Sambre-et-Meuse; and M. Selys de Longchamps makes some additions to a synopsis of the Cordulina.—A programme of five questions for medal competition is announced, the subjects being briefly these: disturbing causes in determination of the electromotive force and inferior resistance of a battery element; relations of heat to the phenomena (especially periodic) of vegetation; embryonal development of Tunicata; composition and mutual relations of albuminoid substances; coal system of the Liège valley.

Archives des Sciences Physiques et Naturelles, Feb. 15, 1874.—In this number M. Dufour gives a detailed account of his researches on the variation of temperature which accompanies diffusion of gases through a porous partition. After describing the apparatus (in which a porous vessel, with thermometer and other tubes inserted in its gutta-percha stopper, was enclosed in a cylindrical glass vessel, and this, enveloped in loose cotton, in a larger earthen vessel), the author studies first the influence of the dry or humid state of gases coming into contact with the porous wall, without diffusion; next, variation of temperature where there is no change of pressure; and third, variation where there is such change. With constant pressure, there is fall of temperature on the side where the denser gas is; and rise on the other side. Each current seems to have a heating effect where it enters the porous wall and a cooling one where it issues. With change of pressure, where this rises within the vessel, through endosmose of a lighter gas, the temperature slightly increases, sinking again as the pressure tends to equilibrium. Where exosmose of a lighter gas causes diminution of pressure in the vessel, the reverse occurs.—From observations of the partial solar eclipse of May 26 last, at three Italian stations, D'Aoste, Moncalieri, and Florence, Prof. Denza finds no sensible influence on the declination needle, either as regards its regular diurnal movement, or the absolute value of its displacement. He is confirmed in the conclusion, previously formed (on data of former eclipses), that no connection has hitherto been demonstrated between the two orders of cosmic facts, eclipses and phenomena of terrestrial magnetism.—M. Charles Lory communicates a note on some facts of structure in the central chains of the Alps.—The *Bulletin Scientifique* gives, as usual, a valuable series of notes on recent progress in Physics, Geology, Zoology, and other branches.

SOCIETIES AND ACADEMIES

London

Royal Society, March 26.—On the Motions of some of the Nebulæ towards or from the Earth, by William Huggins, D.C.L., LL.D., F.R.S.

The observations on the motions of some of the stars towards and from the earth, which I had the honour to present to the Royal Society in 1872, appeared to show, from the position in the heavens of the approaching and receding stars, as well as from the relative velocities of their approach and recession, that the sun's motion in space could not be regarded as the sole cause of these motions. "There can be little doubt but that in the observed stellar movements we have to do with two other independent motions—namely, a movement common to certain groups of stars and also a motion peculiar to each star." *

It then presented itself to me as a matter of some importance to endeavour to extend this inquiry to the nebulæ, as it seemed possible that some light might be thrown on the cosmical relations of the gaseous nebulæ to the stars and to our stellar system by observations of their motions of recession and approach.

Since the date of the paper to which I have referred, I have availed myself of the nights sufficiently fine (unusually few even for our unfavourable climate) to make observations on this point. The inquiry was found to be one of great difficulty, from the faintness of the objects and the very minute alteration in position in the spectrum which had to be observed.

At first the inquiry appeared hopeless, from the circumstance that the brightest line in the nebular spectrum is not sufficiently coincident in character and position with the brightest line in the spectrum of nitrogen to permit this line to be used as a fiducial line of comparison. The line in the spectrum of the nebulæ is narrow and defined, while the line of nitrogen is double, and each component is nebulous and broader than the line of the nebulæ. The nebular line is apparently coincident with the middle of the less refrangible line of the double line of nitrogen. *

The third and fourth lines of the nebular spectrum are undoubtedly those of hydrogen, but their great faintness makes it impossible to use them as lines of comparison under the necessary conditions of great dispersive power, except in the case of the brightest nebulæ.

The second line, as I showed in the paper to which I have referred, is sensibly coincident with an iron line, wave-length 495·7; but this line is inconveniently faint, except in the brightest nebulæ.

In the course of some other experiments my attention was directed to a line in the spectrum of lead which falls upon the less refrangible of the components of the double line of nitrogen. This line appeared to meet the requirements of the case, as it is narrow, of a width corresponding to the slit, defined at both edges, and in the position in the spectrum of the brightest of the lines of the nebulæ.

In December 1872 I compared this line directly with the first line in the spectrum of the Great Nebulæ in Orion. I was delighted to find this line sufficiently coincident in position to serve as a fiducial line of comparison.

I am not prepared to say that the coincidence is perfect; on the contrary, I believe that if greater prism power could be brought to bear upon the nebulæ, the line in the lead spectrum would be found to be in a small degree more refrangible than the line in the nebulæ.

The spectroscope employed in these observations contains two compound prisms, each giving a dispersion of 9° 6′ from A to H. A magnifying-power of 16 diameters was used.

In the simultaneous observation of the two lines it was found that if the lead line was made rather less bright than the nebular line, the small excess of apparent breadth of this latter line, from its greater brightness, appeared to overlap the lead line to a very small amount on its less refrangible side, so that the more refrangible side of the two lines appeared to be in a straight line across the spectrum. This line could be therefore conveniently employed as a fiducial line in the observations I had in view.

In my own map of the spectrum of lead this line is not given. In Thalén's map (1868) the line is represented by a short line to show that, under the conditions of spark under which Thalén observed, this line was emitted by those portions only of the vapour of lead which are close to the electrodes.

I find that by alterations of the character of the spark this line becomes long and reaches from electrode to electrode. As some of those conditions (such as the absence of the Leyden jars, or the close approximation of the electrodes when the Leyden jars are in circuit) are those in which the lines of nitrogen of the air in which the spark is taken are faint or absent, the circumstance of the line becoming bright and long, or faint and short inversely, as the line of nitrogen suggested to me the possibility that the line might be due not to the vapour of lead but to some combination of nitrogen under the presence of lead vapour. As, however, this line is bright under similar conditions when the spark is taken in a current of hydrogen, this supposition cannot be correct.

A condition of the spark may be obtained in which the strongest lines of the ordinary lead spectrum are scarcely visible, and the line under consideration becomes the strongest in the spectrum, with the exception of the bright line in the extreme violet.

I need scarcely remark that the circumstance of making use of this line for the purpose of a standard line of comparison is not to be taken as affording any evidence in favour of the existence of lead in the nebulæ.

Each nebula was observed on several nights, so that the whole observing time of the past year was devoted to this inquiry. In no instance was any change of relative position of the nebular line and the lead line detected.

It follows that none of the nebulæ observed show a motion of translation so great as 25 miles per second, including the earth's motion at the time. This motion must be considered in the results to be drawn from the observations; for if the earth's motion be, say, 10 miles per second from the nebulæ, then the nebula would not be receding with a velocity greater than 15 per second; but the nebula might be approaching with velocity as great as 35 miles per second, because 10 miles of this velocity would be destroyed by the earth's motion in the contrary direction.

The observations seem to show that the gaseous nebulæ as a

* Proceedings of the Royal Society, vol. xx. p. 392.

* Proceedings of the Royal Society, vol. xx. p. 380.

class of bodies have not proper motions so great as many of the bright stars. It may be remarked that two other kinds of motion may exist in the nebulæ, and if sufficiently rapid, may be detected by the spectroscope. 1. A motion of rotation in the planetary nebulæ which might be discovered by placing the slit of the instrument on opposite limbs of the nebulæ. 2. A motion of translation in the visual direction of some portions of the nebulous matter within the nebula, which might be found by comparing the different parts of a large and bright nebula.

Sir William Herschel states that "nebulæ were generally detected in certain directions rather than in others, and the spaces preceding them were generally quite deprived of stars; that the nebulæ appeared some time after among stars of a certain considerable size, and but seldom among very small stars; that when I came to one nebula I found several more in the same neighbourhood, and afterwards a considerable time passed before I came to another parcel." *

Since the existence of real nebulæ has been established by the use of the spectroscope, Mr. Proctor † and Prof. D'Arrest ‡ have called attention to the relation of position which the gaseous nebulæ hold to the Milky Way and the sidereal system.

It was with the hope of adding to our information on this point that these observations of the motions of the nebulæ were undertaken.

In the following list the numbers are taken from Sir J. Herschel's "General Catalogue of Nebulæ." The earth's motion given is the mean of the motions of the different days of observation.

Chemical Society, April 2.—Prof. Odling, F.R.S., in the chair.—A paper on Sulpho-cyanide of Ammonium and Sulphocyanogen, by Dr. T. L. Phipson, and a note On a Reaction of Gallic Acid, by H. R. Procter, were read by the Secretary. Mr. Procter finds that a mixture of gallic acid and potassium arsenate, when exposed to the air, acquires a beautiful green colour.—Mr. W. Noel Hartley then read a memoir On Cobalt Bromides and Iodides, in which he described the method of preparation and properties of these compounds; they closely resemble the corresponding chlorides. Fine specimens of the different salts were exhibited by the author.—Mr. E. Neison read a paper On the Distillation of Sodium Ricinoleate, and Mr. C. H. Piesse a note On the Solubility of Plumbic Chloride in Glycerin.—Mr. Kingzett read a voluminous communication On Ozone as a Concomitant of the Oxidation of the Essential Oils, Part I., and from his experiments he infers that the compound produced during the oxidation of oil of turpentine is neither ozone nor hydrogen peroxide, but a hydrated oxide of turpentine. The last paper was On the Action of Chloride of Benzyl on Camphor, Part II., by Dr. D. Tommasi.

Royal Microscopical Society, April 1.—F. H. Wenham, vice-president, in the chair.—A paper On the Structure of the Lepisma Scale, by Dr. Anthony, was read to the meeting, in which the author showed that the two sets of markings were upon opposite sides of the scale, the ribs being upon the under side.—Mr. Wenham gave a demonstration of his method of measuring the angular apertures of objectives, and explained his mode of stopping out the extraneous rays which were so frequently a cause of error.—Mr. S. J. McIntire read a paper describing the proboscis of a moth (believed to be a South African species) which was furnished with a means of perforating the nectaries of flowers. A mounted specimen was exhibited under one of the Society's instruments in the room, and drawings in illustration of the paper were placed upon the table.

Linnean Society, April 2.—Mr. J. Gwyn Jeffreys, F.R.S., in the chair.—On the Morphology of the Skulls in the Woodpeckers (*Picidæ*) and the Wrynecks (*Yungidæ*), by Mr. W. Kitchen Parker, F.R.S. The present paper is one of a series in hand in which the writer has endeavoured to work out thoroughly the facial characters of certain types of birds in harmony with the views given by Prof. Huxley in his well-known paper on the Classification of the Feathered Types (Zool. Proc. April 11, 1867). His own mode of research is much more like that followed by the distinguished author of that paper than that pursued by ornithologists proper. Without undervaluing their excellent labours, there are many things which are seen first and first understood by the embryologist and not by the zoologist as such. Prof. Huxley, in the paper just referred to, separated the forms now under consideration into his group Coleomorphæ, and gives (p. 467) a very valuable summary of their characters. It was sought in that paper to bring into more or less zoological contiguity such birds as have a similar structure of the facial, and especially of the palatal, bones. Those group-terms, the Schizognathæ (p. 426), the Dromæognathæ (p. 425), &c., are very important, although some of them are of very wide application. It was the first thought of the author of this paper that the woodpeckers would easily find a place amongst the *non-passerine* aërial birds; but examination of their palatal structures soon dispelled this opinion. They are more allied to the Passerinæ than most of the Zygodactyles; but it is to the *embryos* of that type, and not to the adult, that they are related. The Passerinæ themselves are well termed ægithognathous (p. 450); this huge group is under hand at present. Most of the non-passerine birds that seem to come nearest to the woodpeckers have a very solid palate; they are desmognathous; others, as the humming-birds and goatsuckers (*Caprimulgus*), are schizognathous; whilst the swift (*Cypselus*) is as perfectly ægithognathous as the swallows. But the woodpeckers retain that non-coalescent condition of the palatal structure which we see in the lizards, very unlike that great fusion of parts towards the mid-line which occurs in most of the higher birds. They also have an unusally arrested condition of the palatal part of the upper jaw-bone (maxillary), which is characteristic of the lizard and unlike the bird-class generally, and bones superadded to the palate, vomers, septomaxillaries, &c.; these are persistently in paired groups, more in number, and altogether more evidently embryonic and Lacertian, than the homologous parts of other birds. The writer therefore seeks to introduce a new morphological term for these birds as a group, having relation to their face, namely, the term Saurognathæ; for none of Prof. Huxley's terms are appropriate for this type of palate. The writer has worked out these parts in the nestling of *Yunx torquilla*, in four stages of *Gecinus viridis*, in the young of *Picus minor*, and in the adult of *P. major*, *P. analis*, *Hemilophus fulvus*, and *Picumnus minutus*.

MANCHESTER

Literary and Philosophical Society, March 3.—*Physical and Mathematical Section*.—Alfred Brothers, F.R.A.S., president of the Section, in the chair.—Results of Rain-Gauge Observations at Eccles, Manchester, during the year 1873, by Thomas Mackereth, F.R.A.S.

March 10.—Ordinary Meeting.—E. W. Binney, F.R.S., vice-president, in the chair.—The chairman said that at a meeting of the Society on January 9, 1872, in presenting to the notice of the members specimens of fossil woods from the lower coal measures of Lancashire, he stated "that from some examples in his cabinet he was led to believe that Cotta's *Medullosa elegans* was merely the rachis of a fern or a plant allied to one." Prof. Renault, of Paris, to whom we owe so much for his researches in fossil botany, read a memoir before the French Academy on January the 26th last, which has since been printed in the *Comptes Rendus*, that completely confirms this opinion.—Further Observations and Experiments on the Influence of Acids on Iron and Steel, by William H. Johnson, B.Sc. At the last meeting of the Society Prof. Reynolds, in an interesting paper On the Effect of Acid on the Interior of Iron Wire, appears to think that Mr. Johnson did not attribute to hydrogen any portion of the remarkable change produced in iron and steel by immersion in acid. That immersion in acid is the primary cause no one, Mr. Johnson thinks, will dispute; but that hydrogen plays an important part in producing these changes and is the cause of the bubbles, the author showed in a paper read before the Society, March 4, 1873. The supposition that the absorption of hydrogen is the sole cause of the change in the breaking strain, diminution in toughness, &c., attendant on the immersion of iron in hydrochloric or sulphuric acids, and that there is no absorption of

* Philosophical Transactions, 1784, p. 448.
† "Other Worlds than Ours," pp. 280–290.
‡ "Astronomische Nachrichten," No. 1908, p. 190.

these acids into the interior of the iron, does not account for a number of phenomena that have been observed so often and so carefully as to leave no doubt of their invariable recurrence if the conditions of experiment be only properly observed. It seems to the author that the only satisfactory way of explaining all the phenomena is to suppose that when a piece of iron is immersed in acid two actions go on, viz.: an absorption of the nascent hydrogen into the interior of the iron, which hydrogen may subsequently be given off by gentle heat or immersion in a liquid, &c. Secondly, an absorption of the acid itself, possibly in a very concentrated form, by the insterstices between the fibres or crystals of the metal. It will however be said, the acid must act on the walls of the cavity and form a salt of iron with liberation of hydrogen. This may go on to a small extent, but in opposition to this view we may bring the experiments of Prof. Bequerel on solutions separated by a cracked tube (*Comptes Rendus*, lxxvi.), where he shows that no precipitate is formed on placing a cracked tube filled with nitrate of lead in a solution of potassium sulphate within the crack, thus making it probable that chemical interchanges do not take place in very minute spaces. By this theory we may easily explain the decrease in toughness after immersion in acid. For toughness implies a certain ease of mobility of the particles. When a piece of iron is bent the particles of one side are compressed, thus diminishing the minute cavities between the fibres, while those of the other side are stretched, and the minute cavities elongated. If we fill these cavities with a liquid this mobility of the particles is prevented, for the cavities cannot now be diminished in size and the compression of the one side cannot now take place, consequently the piece tears or breaks off just like a piece of frozen rope. It will also explain the acid reaction of the moistened fracture, and further, as hydrochloric acid is much more volatile and of less specific gravity than sulphuric acid, it is only natural to expect that the effect of immersion in hydrochloric acid will pass off more rapidly than of immersion in sulphuric. This experience fully confirms. The author then gives details of a number of experiments and their results bearing on the point under discussion.—Results of certain Magnetic Observations made at Manchester during the year 1873, by Prof. Balfour Stewart, F.R.S.

GLASGOW

Geological Society, March 12.—A paper was read On some Polyzoa from the carboniferous limestone shales near Glasgow, by Prof. Young, F.G.S., and Mr. John Young, vice-president. The authors described a new genus which they had established under the name of *Rhabdomeson*, and which includes at least two species hitherto referred to *Ceriopora*, namely, *C. gracilis* and *C. rhombifera*. The authors also described and exhibited specimens of other two species of polyzoa, the one having the habit of a *Fenestella*, the other of a *Glauconome*, but both showing the remarkable peculiarity of a series of eight denticles projecting horizontally over the cell aperture. For the fenestrated species, they proposed to constitute a new genus—*Stellipora*. The other they retained, meantime, in the genus *Glauconome*.—Mr. Robert Graig read a paper, the first of a series, On the Fossils found in the carboniferous beds around Beith and Dalry, with special reference to the position of their first appearance in the beds. These beds, he remarked, are highly fossiliferous, and occur in the following general order:—(1) Lower limestone, resting upon volcanic ash, 17 fathoms; (2) coal and ironstone measures, resting upon the lower limestone, above 100 fathoms; (3) upper limestone, taking the Swindridge or Highfield "post" as the lower stratum, about 65 fathoms. Mr. James Dairon read a paper on a new species of Retiolites (*Retiolites fibratus*) found by him last summer in the Moffat shales of the Lower Silurian system of the South of Scotland.

PARIS

Academy of Sciences, March 30.—M. Bertrand in the chair. M. de Quatrefages presented to the Academy the second part of his work (written in conjunction with M. Hamy, assistant naturalist in the Muscum) entitled "*Crania ethnica*. The skulls of the human races." The author made additional remarks on fossil human races, calling attention in particular to the race of Cro-Magnon. The characters of this race are well exemplified in the male and female remains discovered at Cro-Magnon in 1868. The male skull is remarkable for its capacity, gauging, according to M. Broca, not less than 1,590 cent. cubes, a number sensibly above the mean of all European populations. With the Cro-Magnon remains the authors class several other specimens of human fossils from the same valley of Vézère, from Bruniquel (caves of Lafaye and Forges), from the south towards the Pyrenees (the cave of Aurignac), and from the cave of Gourdon near Montréjeau. The same race is traced in the Menton skeleton and beyond the Alps in the Cantalupo skulls and in that from Isola del-Liri. In France again male skulls of the same race have been excavated in Mâconnais and Grenelle, while Liège has furnished the celebrated Engis skull. During the quaternary epoch it appears therefore that the Cro-Magnon race had its head-quarters in the south-west of France, particularly in the valley of Vézère, where the intellectual development can be traced from station to station, possibly to the confines of civilisation. The authors think it probable that the earliest representatives of the race will be found in Africa.—M. Pasteur made some verbal observations on M. A. Guerin's recent communication on the pathogenetic rôle of ferments in surgical maladies.—On an apparatus invented by M. Moncoq for the operation of transfusion of blood, by M. Bouley.—On the hydrometric service of the basin of the Seine, by M. Belgrand.—MM. Daubrée and Brongniart presented a report on M. Renault's memoir, entitled "Study of the Genus *Myelopteris*." The reporters consider the conclusions arrived at of sufficient importance to warrant the publication of the memoir in the collections from foreign *savants*.—On the integration of equations to the partial derivatives of the second order, by M. A. Picart.—On the artificial production of the phenomena of gaseous thermo-diffusion of leaves by means of moist porous and pulverulent bodies, by M. Merget. The author concluded by observing that the dynamical utilisation of thermo-diffusive forces would resolve in a simple manner the problem of the direct transformation of solar heat (energy?) into mechanical work.—On some general facts which arise from comparative androgenesis, by M. A. Chatin.—Observations on the disposition of the fibro-vascular bundles in leaves, by M. J. L. de Lanessan.—On a method of photographic enlargement for astronomical observations, by M. C. Zenger. The method proposed is likely to be of service in photographing the forthcoming transit of Venus. The author uses a mirror of long focus instead of a lens to produce the sun's image, and to prevent errors of irradiation and inflexion, proposes to photograph the planet at its moment of passage across a point *h* of a particular meridian of the sun, The enlarging process suggested corrects aberration in the original photograph.—On an electro-automatic whistle for locomotives, by MM. Lartigue and Forest.—On the employment of luminous signals in geodesic operations, by M. Laussedat.—The analysis (mathematical) of an armed and closed electro-magnetic circuit proves that electric induction does not traverse conducting masses, by M. P. Volpicelli.—On the movement of air in pipes, by M. C. Bontemps.—On the action of ammonia on acetone, by MM. Œchsner and Pabst. The authors believe that the reaction gives rise to Staedeler's *acetonine*.—On Egyptian blue, by M. H. de Fontenay.—Experimental researches on the influences which changes of barometrical pressure exert on the phenomena of life, 13th note, by M. P. Bert.

THE ADAPTATION OF OUR UNIVERSITIES TO THE WANTS OF THE AGE

It has given us special pleasure during the last few years to record the efforts made in several of our British Universities and Colleges to adapt their teaching and their appliances for teaching to the present state of knowledge. We have seen what has been done by means of a fraction of the splendid revenues of Oxford, what the princely munificence of her Chancellor is providing for Cambridge, and what public subscriptions aided by judicious liberality on the part of Government have enabled Glasgow to achieve. Let us see what is now being attempted by a University which, though for its years rich in usefulness and fame, even relatively to those just mentioned, is, so far as funds are concerned, in a state approaching to indigence.

A short paragraph in our last number called the attention of our readers to the important step which has just been taken by the University of Edinburgh, with the view of thoroughly adapting its lecture-rooms and laboratories at once to the enormously increased numbers of its teachers and students, and to the ever-growing demands of physical and biological science.

Increase of numbers of teachers and taught would of itself demand a proportionate increase of space, which in Edinburgh must be considerably more than two to one as regards lecture-rooms alone. But when we consider the improvements which have been introduced into the modes of teaching, the imperative necessity for *practical* instruction in addition to lectures and demonstrations; nay more, the desirability of enabling professors not merely to teach what is known, but also, by original research conducted by themselves and their more promising students, to endeavour to extend the boundaries of Science: we see how immense are the issues involved in the step which Edinburgh has just taken.

That it will be successful, no one who knows Scotland and Scotsmen can for a moment doubt. But Scotland is a comparatively poor country—receiving back from the Treasury a much smaller fraction of her taxation than more favoured portions of the empire—and Edinburgh University is, relatively to the number of her students, by far the poorest of even the poor Scottish Universities. It is to be hoped, therefore, that Government aid will be forthcoming, as in the recent case of Glasgow, to eke out the efforts of those who, with as good a cause as could be wished for, and hearty desire to advance it, yet cannot entirely rely on the results of their unaided exertions. All former Edinburgh *alumni*, scattered as they are broadcast over the world, especially in England and in India, must be prepared to acknowledge, by such contributions as they can afford to make, the value of the instruction they have received. Let no one abstain from giving because of the smallness of the sum he can afford; every mite is of importance—let him rather rejoice that he has the opportunity, which appears to occur but once in a century, of contributing to so noble an object.

The story of her last successful endeavour to meet wants to a certain extent akin to those now felt is well told in the following extract from the Programme of the Acting Committee :—

"One hundred years ago, an Appeal was made to the public on behalf of the University of Edinburgh. The number of students was then stated as 'betwixt six and seven hundred,' the inadequacy of the collegiate buildings to the size and importance of the University was pointed out, and it was declared that while in Edinburgh great improvements were going forward on all hands, 'the University fabric alone' remained 'in such a neglected state, as to be generally counted a dishonour to the City of Edinburgh, and to this part of the kingdom.'

"The result of that Appeal was a liberal public subscription, opened in March 1768, which, with the aid of Government, provided the handsome edifice now existing. That building for a long period amply sufficed for all the teaching purposes of the University. But the lapse of a century has produced great changes. During that period the population of the metropolis has been more than trebled; increased facilities for travelling have brought the University within easy reach of all parts of the country; the advantages of a University education have become much more appreciated; the advancement of Science has widely extended the field of academic teaching; and the renown alike of teachers and graduates, whose names will ever be associated with the University of Edinburgh, has increased its fame and reputation throughout the world.

"Thus, the buildings of the University again prove to be wholly inadequate to its necessities. This inadequacy is felt in various ways.

"The number of students attending the University in 1768 was 'betwixt six and seven hundred,' and the number of Professors was 21. In the present Session (1873-4) the number of students is between 1,900 and 2,000, and that of the Professors is 35. The Class-room accommodation has thus become wholly insufficient. The students at present attending the Chemistry, Anatomy, and Natural History Classes number about 300 in each case. The Lecture-rooms are consequently much overcrowded, and great personal discomfort is thus occasioned to both the teachers and the taught.

"But apart from the present buildings being insufficient as regards the students in attendance, the nature of the modern system of teaching in several branches has rendered the existing accommodation altogether unsuitable.

"Since the present University buildings were erected, the whole subject of Practical Chemistry has been added to the course of study. Within the last ten years large and commodious laboratories have been provided in connection with many of the European Universities, and it would be most unfortunate if the University of Edinburgh, which was the first British school to introduce practical instruction in Chemistry into the medical curriculum, were not enabled to carry on satisfactorily this important branch of medical and scientific training.

"Again, the instruction formerly given in Anatomy consisted almost entirely of lectures and demonstrations delivered in the class-room. The changes in Medical education during the last thirty years render it necessary that each student should now pursue for himself the study of Practical Anatomy. The rooms at present in use were not constructed for that purpose, and are lamentably inadequate for the work to be done in them.

"But besides the departments of Chemistry and Anatomy, increased accommodation, in the form of Laboratories, and rooms suited for microscopic and other practical investigation and instruction, is required for the Chairs of Materia Medica, the Institutes of Medicine, Natural History, and Pathology. Nor is it less urgent that much additional accommodation for the apparatus and the Physical Laboratory of the Chair of Natural Philosophy should be provided."

Take these in turn—the last-mentioned first. The Physical Laboratory has been but six years in existence ; simply because it was impossible sooner to find any accommodation for it. One small room was obtained capable of holding a dozen students (at very high pressure). The success of the first year was so great that in the next session more than half of the applicants had to be refused admission ; and as the demand grew, the working time allowed each student per day had to be further and further restricted, till, in the session just concluded, the lowest admissible limit (*one hour per day*) had at first to be adopted, and yet several applications for admission had to be refused. In spite of these drawbacks, much sound work has been done, and many of the Laboratory students have already obtained excellent posts connected with Astronomy, Telegraphy, Engineering, Sugar-refining, &c., mainly on account of the training they have received. The good thus done is to be measured, not by the mere fact of the success of these men in life, but by the fact that their success introduces into practical observatories, workshops, &c., men who have learned the reasons for the manipulations they employ, and who can therefore meet an emergency in ways which no rule-of-thumb teaching could possibly have suggested.

In Anatomy and Chemistry, practical teaching has long been established, and is afforded to every medical student and to such others as study these subjects as parts of a general scientific training. But it is necessary that a great deal more should be done in this direction, especially in the way of affording to advanced students opportunities of cultivating their own powers, and furthering Science by original research. The present arrangements render this possible only to a very limited extent.

Although practical instruction in Physiology, Pathology, and Pharmacology have not formed for so long a period as in Anatomy and Chemistry an integral part of a medical curriculum, yet the University authorities have recognised its importance and have introduced it as far as the meagre space at their disposal would admit. But the increasing demand for a practical training has overcrowded these rooms and made it imperative that additional accommodation should be provided, not only for tuition but for self-training and discovery.

Thus all the practical departments in both the physical and biological sciences urgently demand additional houseroom.

In conclusion, we would again call attention to the fact that one of the great reasons for the present appeal is to be found in the immense success of the University ; its mere numerical growth has far exceeded the accommodation provided. But we would also specially note the fact that, although the scheme has just been launched, the contributions already received or promised amount to the very handsome, though of course utterly inadequate, sum of 60,000*l*. At least 40,000*l*. more, with the equivalent which may reasonably be expected from Government, are required to give us yet another University, furnished at least with buildings which will enable it to preserve for another century its well-deserved but hardly-won fame.

But it must not be forgotten that buildings alone, however perfect, are not sufficient for the work desired. The further extension of the teaching staff must inevitably follow. But questions of this nature, as well as the annual supply of funds for the purchase of apparatus and materials, will, we hope, be effectively treated by the Royal Commission on Science, whose Report on the Scottish Universities, and whose proposals for their adequate endowment, are, in the North at least, anxiously expected.

SCHORLEMMER'S "CHEMISTRY OF THE CARBON COMPOUNDS"

A Manual of the Chemistry of the Carbon Compounds; or, Organic Chemistry. By C. Schorlemmer, F.R.S., Lecturer on Organic Chemistry in the Owens College, Manchester. (London: Macmillan and Co, 1874.)

JUDGING from the rapidity with which text-books on Organic Chemistry have made their appearance of late, it might reasonably be inferred that a good treatise on that subject is much wanted. The student who turns eagerly to the present manual in the hope that the eminent author will help him out of some of his difficulties, and that he will find the subject treated in a novel manner, will however, we fear, feel somewhat disappointed.

The classification adopted by the author deals first with the compounds of carbon with oxygen, sulphur, and nitrogen ; compounds which form the connecting link between inorganic and organic chemistry.. He considers, justly, that a knowledge of the compound radicals into which these elements enter is essential to a proper understanding of a large number of other carbon compounds. He then describes the large group of fatty substances, subdivided again according to the quantivalence of their radicals, as well as the carbohydrates, terpenes, and camphors. The next division comprises compounds richer in carbon than the fatty substances, and which are not converted into such by the addition of hydrogen. These are again subdivided into several groups, including that of the aromatic compounds, which has been most fully investigated, and the group of compounds containing two or more aromatic nuclei linked together by carbon, and the glucosides. Lastly, we have a division of artificial and natural bases (alkaloids), of colouring and bitter principles, of compounds contained in bile and other secretions of the animal body, and of albumenoids and proteids.

It will be seen from this brief synopsis that the author deviates for the most part from the arrangement which has found favour with many modern writers on Organic Chemistry. Rather than treat of well-defined families of organic bodies, such as hydrocarbons, alcohols, ethers, aldehydes, ketones, acids, &c., he prefers to retain groups of homologous series, together with their derivatives. To the student this arrangement has the decided drawback that it involves much repetition in examining chemical changes, and, what is more important, it does not enable him to take in at a glance in what consists the similarity or dissimilarity between classes of bodies of analogous structure, and derived from a homologous parent stock ; nor is it so easy to see where one or several links in the various homologous series are miss-

ing. The reward of grappling with the intricacies of organic bodies to which each worker is entitled who adduces new facts—no matter to how limited an extent—consists just in the intellectual treat of supplying perhaps some of these many missing links. There can be no question which system of classification will assist him to do this most speedily.

A student's perplexity will not be diminished on following our author into the vexed question of formulæ. We take it for granted that chemical formulæ have been devised to express the phenomena produced by the action of chemical force. That they express at present the final results rather than the agencies and forces which have been at work to produce them may likewise be taken as correct. They are, at the very best, poor representations only of the chemical changes which we witness daily. Whether it will ever be possible to prove that the atoms or groups of atoms of which chemical compounds are supposed to consist really stand to each other in certain definite relations, because they exhibit certain analogies under the influence of the chemical force which holds them together or loosens them, may well remain matter for speculation. As long as no differences of opinion respecting chemical facts are involved, views may differ on the mode of expressing them by formulæ, provided always that the choice between two different modes of expression falls upon the one which recalls the greatest number of analogies in the most simple and rational manner, and can therefore become more fruitful in new discoveries. Several rational formulæ are possible for one and the same compound according as different relations are to be expressed. A knowledge of the order or position of the atoms is out of the reach of experimental demonstration. If the so-called position-theory of the carbon atoms in certain organic compounds can assist us, however, in elucidating certain relations and analogies, and if this theory is leading rapidly to numerous new discoveries, then, by all means, let us avail ourselves of it. It seems that constitutional, or, as they are sometimes called, structural formulæ excite the ire of some of our critics of chemical literature inversely to the understanding they display of them, and the very name constitutional formula, or the sight of a graphic representation thereof, inflames their fury as violently as a red cloak excites an infuriated bull. However much ridicule may attach in the eyes of some people to constitutional or structural representation, it is pleasant to observe that the chemists who now dispense with it altogether form the exception rather than the rule.

Mr. Schorlemmer makes an especially liberal use of structural formulæ, showing the relative position and units of combining capacity of carbon atoms, with the view mainly of explaining isomeric bodies. Every student of organic chemistry will thank him for this, for, on perusing the journal of the Berlin Chemical Society, for instance, one cannot help being struck with the remarkable impulse which the conception of structural representation of the chemical composition of bodies has given to the study of organic chemistry in Germany. Chemists find it, no doubt, difficult to disengage themselves entirely from some of the various theories that have held sway during the last twenty years, and hence we look with leniency upon the want of uniformity of formulæ and chemical nomenclature displayed in this book. On pp. 3, 4, and 5, for instance, the brace is used in a double sense, showing the formation of molecular bodies by the direct combination of element with element as in $\left.\begin{matrix}H\\H\end{matrix}\right\}, \left.\begin{matrix}H\\Cl\end{matrix}\right\}, \left.\begin{matrix}K\\I\end{matrix}\right\}$; and again by uniting two or more elements with a polyvalent element, as in $\left.\begin{matrix}H\\H\\H\end{matrix}\right\}N$, without any connection existing between the monad elements themselves other than through the polyad element. Such names as Tin chloride, $SnCl_4$, Platinum chloride, $PtCl_4$, and others, must create the impression that these are the only compounds which tin, &c. forms with chlorine. The different atomic groups in structural formulæ are sometimes separated by points, sometimes by lines (forks, prongs, or whiskers, as some fastidious critics have called them). In the absence of these various graphic representations free use is made of molecular formulæ; indeed it strikes us that the author has been often over-cautious, and has not attempted constitutional formulæ where such representation would appear of particular interest to the student, as, for instance, in the case of the isomers of aldehyde, of aldines, &c.

Certain groups of atoms contained in a great number of organic bodies, such as nitroxyl, NO_2, sulphuryl, SO_2, phosphoryl, PO, *may* be viewed otherwise than as monad, dyad, or triad compound radicals. Why, for instance, should PO in phosphorous acid be a triad radical when one of the hydrogen atoms is not replaceable, but "remains together" with the PO group? or in hypophosphorous acid, where two atoms of hydrogen remain linked to PO? Considering the liberality displayed by the author regarding formulæ, we shall be pleased to see him shake off the trammels which still encumber his inorganic compounds. We cannot see why NO_2 should combine with OH to form nitric acid, and with H to form nitrous acid, or why SO_2 should form the compound radical in $SO_2\left\{\begin{matrix}Cl\\Cl\end{matrix}\right.$ and in sulphuric acid $SO_2\left\{\begin{matrix}OH\\OH\end{matrix}\right.$, and also in sulphurous acid $SO_2\left\{\begin{matrix}H\\OH\end{matrix}\right.$. Our author writes ethyl nitrite $C_2H_5O.NO$, and not $C_2H_5NO_2$, "because in the former the N is linked to the ethyl by means of an atom of oxygen, whilst in the isomeric nitro ethane $C_2H_5N\left\{\begin{matrix}O\\O\end{matrix}\right.>$ the nitrogen is linked directly, and the oxygen atoms satisfy each other." We need scarcely say that this latter compound may also be viewed differently. We might greatly extend the list of similar incongruities, taking our examples especially from the organic silicon and boron compounds, which, more than anything else, show that the same idea of grouping elements that is now so freely admitted to prevail for carbon compounds must logically hold good also for inorganic bodies.

The nomenclature first proposed by Hofmann and adopted by our author of designating the different parallel hydro-carbon seri s by the terminations, ane, ene, ine, one, une has some inconveniences which perhaps are less apparent to the teacher than to the student of organic chemistry, who must be sorely puzzled to distinguish, for instance, between ethine and phosphine, stibine, oxytetraldine, &c.; and it is with regret we see some authors

go even further, and substitute, for instance, iodethane for the familiar ethyl iodide, &c.

As constitutional or structural formulæ are intended to assist the student in the study of organic chemistry, we should have preferred if the well-understood abbreviations for compound radicals, advocated by some of our most eminent chemists, such as Et. for ethyl, Ay. for amyl, had been used. We observe, on p. 53, that Cfy. and Cfdy. are used for the compound cyanogen radicals; why should not constitutional formulæ generally be simplified by the use of abbreviations? The task of deciphering certain complex organic formulæ is already heavy enough, and some such shorthand expressions as the above will soon become all but indispensable. We do not for a moment blame the author alone for these sins of omission and commission. Our nomenclature and terminology are in such a state of confusion that a bold reformer should be welcomed rather than discouraged by every lover of our science.

We notice a few slips: On p. 7 "$C_n H_2 + _2$" should be $C_n H_{2n} + _2$; on p. 13 "monad and triad radicals cannot be isolated;" but at top of p. 14 we are told that "methyl combines with methyl, and we obtain ethane or ethyl hydride." Why methyl, &c., should not exist in a free or molecular state as much as hydrogen we are unable to see. On p. 67, the oxygen in the formula for guanidine should be omitted. On p. 72, "methyl iodide $2CH_3$" should be $2CH_3I$. On p. 111, "The vapour of ether is 2·557 times heavier than water." On p. 112 "triacetyl chloride" should be trichloracetyl chloride. On p. 135, "$C_6 H_{12} N$" is given in the equation, instead of $C_6 H_{12} N_2$. On p. 309, "$C_2 H_3 NH_2$" should be $C_2 H_5 NH_2$; and others which we will not mention.

We freely admit many commendable features in Mr. Schorlemmer's new book, which will render it extremely useful, especially to the student engaged in tracing the various isomerides, but we cannot help thinking that in some respects it does not come up to some works on organic chemistry which we already possess.

OUR BOOK SHELF

Dahomey as it Is: being a Narrative of Eight Months' residence in that country, with a full account of the notorious Annual Customs and the Social and Religious Institutions of the Ffons; also an Appendix on Ashantee, and a Glossary of Dahoman Words and Titles. By J. A. Skertchly. (London: Chapman and Hall, 1874).

MR. SKERTCHLY left England in 1871 for the purpose of making zoological collections on the West Coast of Africa. On his arrival at Whydah he was induced to go up to Abomey, the capital of Dahomey, for the purpose of instructing the king, Gelelé, in the use of some guns that had arrived, on the promise that he would be back at Whydah in eight days. The king, however, detained Mr. Skertchly as an unwilling guest for eight months, treating him with the greatest consideration and kindness, and creating him a prince of the country. The greater part of Mr. Skertchly's work is occupied with a description of the protracted annual "customs," as they are called, of Dahomey, which consist of elaborate and harmless trivial ceremonies, mixed up with much that is revolting and cruel; the details of these Mr. Skertchly describes in minute and often tiresome detail. We do not think there was any need for Mr. Skertchly making so large a book on what he saw, especially as the Dahomans and their "customs" are pretty well known through previous travellers. He often questions the accuracy of Burton, who is quite able to defend himself if he feels aggrieved at Mr. Skertchly's criticisms. The author succeeded, during his stay at Abomey, in doing but little in the way of collecting, and in this work there is scarcely any details as to the natural history of the country. He has evidently a considerable admiration both for the Dahomans and Ashantees, especially for the former, whom he considers not nearly so cruel as the latter, though both equally brave and remarkably well-disciplined as soldiers. In a short Appendix on the Ashantees, he prophecies that our recent expedition to the Gold Coast would find them formidable enemies, which prophecy can hardly be said to have been fulfilled. He defends the Dahomans from the charge of intentional cruelty in the barbarously performed human sacrifices which form so important a part of their customs, and we think he succeeds; the victims, who are all either criminals, or prisoners of war, are sent as messengers to deceased kings. The work is illustrated with a number of gorgeously coloured plates, which no doubt show faithfully the dresses and manners of the people, though some of the pictures which exhibit the method of sacrificing the human victims are simply revolting, and ought to have been confined to the author's portfolio.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Fertilisation of the Fumariaceæ

I BEG permission to make a few remarks on Mr. J. Traherne Moggridge's statement (NATURE, vol. ix. p. 423) that the flowers of *Fumaria capreolata* are at first pale or nearly white, and only attain their brightest colouring, becoming even crimson, after the ovaries are set. He then adds:—"If the reverse had been the case there is little doubt that we should have regarded the bright colouring as specially adapted to attract insects." But does Mr. Moggridge know that these flowers are visited chiefly by diurnal insects? It has often been observed that flowers which are visited by moths are commonly white or very pale; but if they are odoriferous, they may be of any tint, even very dark or green. If therefore the flowers of the above Fumaria are visited by moths, it would be an injury to the plant had the flowers been from the first of a fine crimson. I have often seen bees sucking the flowers of the fumariaceous genera, *Corydalis*, *Dielytra*, and *Adlumia*; but many years ago I watched perseveringly the flowers of *Fumaria officinalis* and *parviflora*, and never saw them visited by a single insect; and I concluded from reasons which I will not here give (as I cannot find my original notes), that they were frequented during the night by small moths. Insects are not necessary for the fertilisation of *Fumaria officinalis*; for I covered up a plant, and it produced as many seeds as an uncovered one which grew near. On the other hand, with some species of *Corydalis*, the aid of insects is indispensable. With respect to the flowers of *F. capreolata* becoming brighter coloured as they grow old, we see the same thing in some hawthorns, and with the double rocket in our gardens. But is it surprising that this should sometimes occur with flowers, seeing that the leaves of a multitude of plants assume, as they become oxygenised, the most splendid tints during the autumn?

Down, Beckenham, Kent, April 6 CHARLES DARWIN

IN the vegetable kingdom we meet very commonly with gaily-coloured chemical products, essentially connected with the normal processes of development (the chlorophyll of most non-parasitic plants, the splendid rose pigments of Florideæ, the many lively-coloured pigments of lichens and fungi), and originating from venomous infection by insects (red-coloured galls of oak-leaves) or from decomposition (red pigments in autumnal leaves). In all these cases these colours appear to us to be merely an accidental quality of the chemical products, and we do not feel induced to start the question of what use any particular colour may be to the plant producing it. But it is quite otherwise with the gay colours of flowers. Bright colours in flowers which especially attract our attention and admiration are in most cases beneficial to the plant itself which produces

them, by attracting in like manner also the attention of insects, which, visiting the flowers for their own profit, at the same time unconsciously bring to the plant the great advantage of cross-fertilisation. Hence we understand that bright-flowered varieties, whenever produced by any cause, might be preserved by natural selection, and at last remain the only survivors among all the concurrents of the same species. Thus, the occasional appearance of gaily-coloured varieties granted as a matter of fact, and the peculiarities of colour supposed to be hereditable, we are enabled by Darwin's theory to explain the variety of colours met with in flowers. But we should always bear in mind that we are at present quite ignorant of the chemical processes by which certain colours are produced in the flowers, and of the physical or organic causes by which these chemical processes were effected when they first appeared and are effected in every subsequent generation. Reflecting on the first origin of the adaptation of flowers to the cross-fertilisation by insects, and considering that the oldest and most primitive phanerogamous plants which still exist, the Gymnospermæ, are exclusively fertilised by the wind (are *anemophilous*), whilst the enormous majority of Angiospermæ is provided with flowers adapted to cross-fertilisation by insects (*entomophilous*), we cannot doubt that the original manner of fertilisation of phanerogamous plants was fertilisation by the wind, and that the first plants which adapted their flowers to cross-fertilisation by insects were anemophilous ones, either Gymnospermæ or the next descendants of them. Nevertheless the flowers of many Gymnospermæ (Abietinæ) present a beautiful colour, which attains its culmination during the disseminating of the pollen.* This beautiful colour is apparently neither of any use to these plants, which are regularly cross-fertilised by the wind, nor can have been inherited from ancestors to which it was useful. We may therefore also in this case, without hesitation, regard the colour as a merely accidental phenomenon, which, secondarily produced by the more active chemical processes during the time of flowering, disappears again in the same degree as the intensity of development decreases in the cones. Probably the gaily-coloured perianths of the entomophilous Angiospermæ have originated in a similar manner.

Independently of possible physical effects, natural selection is evidently without any influence as to colours, unless animals are attracted or repelled by them. Consequently not only the first origin of bright-coloured flowers, but also the change of colour in the flowers after the ovaries are set, is altogether foreign to the effects of natural selection. It is as indifferent to an entomophilous plant whether its flowers, after having been fertilised, grow paler or darker, as it is to an anemophilous plant whether its flowers are attractive to insects or not. In most cases, indeed, flowers change while fading into paler and less conspicuous colours, but often also their colour remains unaltered or even grows more conspicuous. Old flowers of *Melampyrum pratense*, for instance, which, not having been cross-fertilised by insects, regularly fertilise themselves, are always reddish-yellow, whilst younger ones are yellow.

As to *Fumaria capreolata*, alluded to in Mr. Moggridge's letter (NATURE, vol. ix. p. 423) I have never had the opportunity of observing its flowers myself, but from Hildebrand's account ("Jahrb. f. wissensch. Bot." vii. p. 452) I believe that it is restricted to regular self-fertilisation, cross-fertilisation by insects not, indeed, being impossible, but taking place very exceptionally; for it has lost, probably from permanent disuse, the elasticity of the cap formed by the inner petals, which in other fumitories secures cross-fertilisation in case of the repeated visits of insects. If this presumption of mine be right, it would the more explain Mr. Moggridge's observation; for in this case the colour of the flowers of this fumitory, inherited from ancestors to which it was quite useful, would be almost useless to this degenerated descendant, and therefore almost withdrawn from the influence for natural selection.

Conference for Maritime Meteorology

SOME of your readers may have noticed in the Report of the Proceedings of the Meteorological Congress at Vienna that it was decided to be advisable to convene a fresh Conference for maritime meteorology, in order to reconsider the decisions of the Brussels Conference in 1853.

The matter was handed over to the Permanent Committee, and by them delegated to a sub-committee composed of the following members:—

Prof. Buys Ballot (Holland)
Prof. Mohn (Norway)
Capt. E. Mouchez (France)
Dr. G. Neumayer (Germany)

with myself.

The sub-committee have nearly decided on a form of programme for the proceedings, and there are hopes that the Conference will meet in London in the month of August or so. Endeavours will probably be made to induce H.M.'s Government to issue the invitations, and thereby to give an official character to the Conference.

ROBERT H. SCOTT

Herbert Spencer and *à priori* Truths

ABSENCE from town has delayed what further remarks I have to make respecting the disputed origin of physical axioms.

The particular physical axiom in connection with which the general question was raised, was the Second Law of Motion. It stands in the *Principia* as follows:—

"*The alteration of motion is ever proportional to the motive force impressed; and is made in the direction of the right line in which that force is impressed.*

"If any force generates a motion, a double force will generate double the motion, a triple force triple the motion, whether that force be impressed altogether and at once, or gradually and successively. And this motion (being always directed the same way with the generating force), if the body moved before, is added to or subducted from the former motion, according as they directly conspire with or are directly contrary to each other; or obliquely joined, when they are oblique, so as to produce a new motion compounded from the determination of both."

As this, like each of the other laws of motion, is called an axiom;* as the paragraph appended to it is simply an amplification, or re-statement in a more concrete form; as there are no facts named as bases of induction, nor any justifying experiment; and as Newton proceeds forthwith to draw deductions, it was a legitimate inference that he regarded this truth as *à priori*. My statement to this effect was based on the contents of the *Principia* itself; and I think I was warranted in assuming that the nature of the laws of motion, as conceived by Newton, was to be thence inferred.

The passages quoted by the *British Quarterly Reviewer* from Newton's correspondence, which were unknown to me, show that this was not Newton's conception of them. Thus far, then, my opponent has the best of the argument. Several qualifying considerations have to be set down, however.

(1) Clearly, the statements contained in the *Principia* do not convey Newton's conception; otherwise there would have been no need for his explanations. The passages quoted prove that he wished to exclude these cardinal truths from the class of hypotheses, which he said he did not make; and to do this he had to define them.

(2) By calling them axioms, and by yet describing them as principles "*deduced* from phenomena," he makes it manifest that he gives the word axiom a sense widely unlike the sense in which it is usually accepted.

(3) Further, the quotations fail to warrant the statement that the laws of motion are proved true by the truth of the *Principia*. For if the fulfilment of astronomical predictions made in pursuance of the *Principia* is held to be the evidence "on which they chiefly rest to this day," then, until thus justified, they are unquestionably hypotheses. Yet Newton says they are not hypotheses.

Newton's view may be found without seeking for it in his letters: it is contained in the *Principia* itself. The scholium to Corollary VI. begins thus:—

"Hitherto I have laid down such principles as have been received by mathematicians, and are *confirmed* by abundance of experiments. By the two first Laws and the two first Corollaries, Galileo discovered that the descent of bodies observed the duplicate ratio of the time, and that the motion of projectiles was in the curve of a parabola; experience *agreeing* with both," &c.

Now as this passage precedes the deductions constituting the *Principia*, it shows conclusively, in the first place, that Newton did not think "the whole of the *Principia* was the proof" of the

* It is true that in Newton's time, "axiom" had not the same rigorously defined meaning as now; but it suffices for my argument that, standing unproved as a basis for physical deductions, it bears just the same relation to them that a mathematical axiom does to mathematical deductions.

laws of motion, though the Reviewer asserts that it is. Further, by the words I have italicised, Newton implicitly describes Galileo as having asserted these laws of motion, if not as gratuitous hypotheses (which he says they are not), then as *à priori* intuitions. For a proposition which is *confirmed* by experiment, and which is said to *agree* with experience, must have been entertained before the alleged verifications could be reached. And as before he made his experiments on falling bodies and projectiles, Galileo had no facts serving as an inductive basis for the Second Law of Motion, the law could not have been arrived at by induction.

Let me end what I have to say on this vexed question by adding a further reason to those I have already given, for saying that physical axioms cannot be established experimentally. The belief in their experimental establishment rests on the tacit assumption that experiments can be made, and conclusions drawn from them, without any truths being postulated. It is forgotten that there is a foundation of preconceptions without which the perceptions and inferences of the physicist cannot stand—*preconceptions which are the products of simpler experiences than those yielded by consciously-made experiments.* Passing over the many which do not immediately concern us, I will name only that which does,—the exact quantitative relation between cause and effect. It is taken by the chemist as a truth needing no proof, that if two volumes of hydrogen unite with one volume of oxygen to form a certain quantity of water, four volumes of hydrogen uniting with two volumes of oxygen will form double the quantity of water. If a cubic foot of ice at 32° is liquefied by a specified quantity of heat, it is taken to be unquestionable that three times the quantity of heat will liquefy three cubic feet. And similarly with mechanical forces, the unhesitating assumption is that if one unit of force acting in a given direction produces a certain result, two units will produce twice the result. Every process of measurement in a physical experiment takes this for granted; as we see in one of the simplest of them—the process of weighing. If a measured quantity of metal, gravitating towards the earth, counterbalances a quantity of some other substance, the truth postulated in every act of weighing is, that any multiple of such weight will counterbalance an equi-multiple of such substance. That is to say, each unit of force is assumed to work its equivalent of effect in the direction in which it acts. Now this is nothing else than the assumption which the Second Law of Motion expresses in respect to effects of another kind. "If any force generates a motion, a double force will generate a double motion," &c., &c. ; and when carried on to the composition of motions, the law is, similarly, the assertion that any other force, acting in any other direction, will similarly produce in that direction a proportionate motion. So that the law simply asserts the exact equivalence of causes and effects of this particular class, while all physical experiments *assume* this exact equivalence among causes and effects of all classes. Hence, the proposal to prove the laws of motion experimentally, is the proposal to make a wider assumption for the purpose of justifying one of the narrower assumptions included in it.

Reduced to its briefest form the argument is this:—If definite quantitative relations between causes and effects be assumed *à priori*, then, the Second Law of Motion is an immediate corollary. If there are not definite quantitative relations between causes and effects, all the conclusions drawn from physical experiments are invalid. And further, in the absence of this *à priori* assumption of equivalence, the quantified conclusion from any experiment may be denied, and any other quantification of the conclusion asserted.

HERBERT SPENCER

MR. SPENCER's letter in NATURE, vol. ix. p. 420, is likely to give to such of your readers as have not followed the controversy in which he is engaged a false notion of the issues therein. Mr. Spencer writes as though the views of the nature of physical truth that were objected to by Prof. Tait and myself amounted to the ascription of our knowledge of sundry physical laws to organised ancestral instead of individual experiences. In one portion of his reply to me he intimates the same, as, for instance, where he says of me:—

"His argument proceeds throughout on the assumption that I understand *à priori* truths after the ancient manner as truths independent of experience; and he shows this more than tacitly where he 'trusts' that he is attacking one of the last attempts to deduce the laws of nature from our inner consciousness. Manifestly a leading thesis of one of the works he professes to review is entirely unknown to him—the thesis that forms of thought, and consequently those intuitions which those forms of thought involve, result entirely from the effects of experiences organised and inherited" ("Replies to Criticisms," p. 332).

But, in his "First Principles," Mr. Spencer expresses himself far too clearly for him to be able to assign the above as his views at that time on these so-called *à priori* truths. Speaking of the indestructibility of matter, one of the three truths in question, he says:—

"The annihilation of matter is unthinkable for the same reason that the creation of matter is unthinkable—and its indestructibility thus becomes an *à priori* cognition of the highest order—*not one that results from a long continued registry of experiences gradually organised into an irreversible mode of thought;* but one that is given in the form of all experiences whatever."

For the second of the truths he claims a similar authority; while for the third—the Persistence of Force—he claims a yet higher warrant:—

"Deeper than demonstration—deeper even than definite cognition—deep as the very nature of mind is the postulate at which we have arrived (*i.e.* the Persistence of Force). *Its authority transcends all other whatever; for not only is it given in the constitution of our own consciousness*, but it is impossible to imagine a consciousness so constituted as not to give it." ("First Principles," p. 192).

Had Mr. Spencer confined himself to defending such an *à priori* origin of physical truths as he now seems inclined to put forward, I should never have compared his theories to those of the Ptolemaists. But I can leave it with confidence to the readers of NATURE to decide between us as to whether the above passages do not show that at the time when they were written Mr. Spencer understood *à priori*, as there applied, in a manner very like the "ancient manner," and whether he did not maintain that these *à priori* truths were indeed "truths independent of experience."

THE AUTHOR OF THE ARTICLE ON HERBERT SPENCER IN THE BRITISH QUARTERLY REVIEW

[The Editor, very properly wishing, I doubt not, to end the controversy, has sent to me the foregoing letter in proof. My comment on it is very brief.

Had the reviewer read the "Principles of Psychology," placed at the head of his article apparently for form's sake only, he would, not, I think, have made the above rejoinder.

That view of the *à priori* origin of physical truths which the Reviewer now seems to think defensible is the view implied in "First Principles" and the view set forth in the "Principles of Psychology," published years before. Tacitly throughout that work, and explicitly near the end, in a chapter on "Reason," the doctrine is that the "forms of thought" themselves are the products of experience. If the nervous system as a whole and in all its structures has been evolved by converse between the organism and the environment, the fundamental principles of its action, the very "forms of all experiences" have been evolved. Experience itself grew into definiteness gradually. And if the very form of our thought, the very frame-work of our consciousness, has been thus moulded, the inability to conceive a mode of thinking fundamentally different, is simply the result of inability to invert the fundamental action of the structures by which we think.—H. S.]

On the Word "Axiom"

IN reference to the controversy between Mr. Spencer and his reviewer about Sir I. Newton's calling his laws of motion "axioms," it is to be observed that there is a certain ambiguity in the word. "Axiom" is from ἀξιόω (I demand), and would thus signify a first principle to be taken for granted. It does not, of course, carry with it the meaning of a necessary judgment which cannot be contradicted. Whatever may be considered the ground of Euclid's "axioms" so called, Euclid himself did not apply that name to them; but the first nine he called "common notions," and the last three (which are peculiar to geometry) he placed among the postulates (ὁμολογήματα), and heads them with "let it be granted." Now it is clear, from Newton's own words, that in calling his Leges motûs "axioms," he does not imply that they are *necessary* judgments, but that he requires them first of all to be granted (however established) in order to the following reasoning. In other words, they are postulates, like Euclid's last three "axioms." In our modern use of the words "axiom," "axiomatic," there is always implied the *ground* why a proposition is demanded as granted, viz., because its necessity is self evident; but this wider use is not required by etymology, or (I think) in interpreting all ancient writings.

F.M.S.

A Beech pierced by a Thorn Plant

THE word *pierced* makes the difference between an impossibility and a fact which is not uncommon in nature. The thorn mentioned in your last impression by Mr. Murphy has grown between two beech stems, which were so close that from their annual increase they grew together, and in so doing they enclosed the thorn, which could no more have *pierced* the beech than it could have pierced a block of marble. If young trees are twisted together they will grow together. Years ago I placed a bar of iron in an interstice between two stems so twisted, in another interstice below it I placed a part of the drag-chain of a waggon. According to Mr. Murphy the two iron appendages "have grown right through the middle of the trunks of the two beeches." They are at least as firmly fixed as if they had done so.

The tree with the iron branches is close to the lodge on Brookwood Hill. Should any of your readers consider it to be worth inspection, the lodge-keeper will show it to them.

April 11 GEORGE GREENWOOD

Mars

I BEG to offer my thanks to Mr. Knobel for his obliging correction (vol. ix. p. 396) with regard to the contrasted tint of the snow-poles of Mars. His observations had quite escaped my recollection.

I have also to mention a correction with which I have been favoured by the Earl of Rosse. It appears that an erroneous hour had been affixed to the drawing of Mars made at Parsonstown on September 14, 1862, and engraved in Mem. R.A.S., vol. xxxii., pl. v., and that an explanation is thus offered of one of the discrepancies commented on by Prof. Kaiser.

Cheltenham, April 9 T. W. WEBB

Bright Shooting-star

A SHOOTING-STAR, equal in apparent brightness to the planet Jupiter, was seen here by me this evening at $9^h 18^m$. It traversed a path of 24° in two seconds, beginning at R.A. 242°, D + 47°, and ending at R.A. 278°, D + 50°. No perceptible train remained after the disappearance of the nucleus, which, however, emitted numerous sparks when in motion. The radiant point of this meteor was probably near β Boötis, and identical with No. 36 in Mr. R. P. Greg's table of radiant positions in the "Monthly Notices R.A.S.," vol. xxxii. p. 350. This is given at R.A. 223°, D + 40° by Greg and Herschel, and at R.A. 224°, D + 38° by Schiaparelli and Zezioli. The meteor described above was not therefore a member of the well-marked meteoric streams of April 18–20. At stations eastward it was probably a much brighter object than observed here, and these brief details may be useful, taken in conjunction with others, in determining its height and velocity.

Cotham Park, Bristol, April 11 WILLIAM F. DENNING

THE LATE DR. LIVINGSTONE

OUR readers are no doubt familiar through the daily press with all that has transpired during the past week in reference to the all-absorbing topic of the late Dr. Livingstone and the home-bringing of his remains. The coffin containing these arrived at Southampton yesterday morning, and was received by the Corporation, Livingstone's family and friends, the President and fellows of the Royal Geographical Society, and many others, with all solemnity and with every mark of genuine respect. The body of the great explorer was accompanied to the station by a long and distinguished procession, and was conveyed in a special train to London, to be buried in Westminster Abbey on Saturday at 1 P.M.

The proposed position of the grave in the Abbey is near that of Major Rennel, the father of English geography, and the friend and adviser of Mungo Park. There was some hesitation between this position and the one near the grave of Sir John Chardin, the Persian traveller.

The President of the French Geographical Society, Vice-Admiral Baron de la Ronciere le Noury, is coming over from Paris, for the express purpose of being present at the funeral.

The Government grants a sum which Sir Bartle Frere "trusts will be sufficient for all purposes." Still we are glad to have Sir Bartle Frere's assurance that in the end there will be "no shortcoming on the part of the Government."

Dr. Livingstone's vocation was not a money-making one; he did not even live to hear that the world ranked him among its greatest men; the end of all his labours was a sad one. This country, all civilised countries we may say, will attend to the appeal which has been made on behalf of his family.

As was to be expected, Scotsmen have taken the initiative in raising a monument to one of the greatest of their fellow-countrymen; at a meeting held at Edinburgh, on Tuesday, it was resolved, in recognition of the "heroic services rendered to science and civilisation by the late Dr. Livingstone," that a national statue be erected to his memory in the capital of his native country. This is right and it is honourable to his fellow-countrymen, though the memory of Livingstone will need no "labour of an age in piled stones" to render it immortal. Indeed a true idea of the full height of his greatness is only as yet beginning to dawn gradually upon us, and it will be some time ere we are able adequately to estimate it. No doubt, therefore, the thought contained in Tennyson's sad strain must have occurred to many a one during the last few weeks—

"I would that my tongue could utter
The thoughts that arise in me;"

and perhaps with still greater force those others—

"Oh for the touch of a vanished hand
And the sound of a voice that is still."

What honours would we have heaped upon his head had he only lived to reach his native shore!

NATIONAL MUSEUMS IN BRAZIL

THE working of the National Museums in Brazil seems to be conducted on similar principles to those recently advocated for the management of the Government Museums in this country. From a thick volume of 388 pp. explanatory of the topography, constitution, and resources of Brazil, issued in connection with the Brazilian Department of the late Vienna Exhibition, we gather that the most important Natural History Museum in South America, is that at Rio de Janeiro, which was founded in 1817. It is divided into four sections:—the first includes Comparative Anatomy, Physiology, and Zoology; the second Botany, Agriculture, and the Mechanical Arts; the third Mineralogy, Geology, and the Physical Sciences; and the fourth Numismatics, Archæology, &c. Each section has its separate director, who has assistants, and the whole Museum is presided over by a Director-in-Chief. "The Museum has, besides, several corresponding members in the National and Foreign Scientific Societies, and there are two naturalists travelling through the Empire, for the purpose of making collections.

"The principal object of the National Museum is, to collect and study all the natural products of the country, and to deliver public lectures on the science of its province, spreading among the people theoretical and practical knowledge, in a simple style, adapted to their comprehension.

"The Museum," it is stated, "now keeps up a correspondence with European establishments of the same description, and willingly exchanges duplicates of its collections for those of foreign museums.

"The Government intends to create in the provinces several museums independent of that in the capital of the empire, that they may exchange among one another the respective products of each one, receiving at the same time from the central one, not only the necessary instructions for the classification and study of the collections, but its superabundant duplicates."

POLARISATION OF LIGHT*

VII.

AMONG the phenomena of polarised light which may be observed either with a Nicol's prism or even with the naked eye, one of the most curious, and perhaps not yet fully explained, is that of Haidinger's brushes. If the eye receives a beam of polarised light a pale yellow patch in the form of an hour-glass, the axis of which is perpendicular to the plane of vibration, is perceived. On either side of the neck of the figure two protuberances of a violet tint are also seen to extend. After a little practice these figures or "brushes" may readily be observed. If the day be cloudy a Nicol must be used and directed to a tolerably bright cloud. The brushes are better defined in one position than in others; but if the Nicol be turned round, the brushes will be seen to revolve with it. If on a clear day we look in a direction at 90° from that of the sun, where the skylight is most completely polarised. the brushes may be seen with a naked eye. Jamin has suggested in explanation of this phenomena that the substances of the eye act like a pile of glass plates, or rather spheres, which affect in different degrees (1) the rays of the same colour whose vibrations are differently inclined to the plane of incidence, and (2) the rays of different colours whose vibrations are similarly inclined. This will cause one colour to predominate in a general direction parallel, and its complementary to predominate in a plane perpendicular, to that of vibration. Helmholtz, however, connects the phenomenon with some double refraction due to the yellow spot in the eye, with the area of which that of the brushes is coincident.

It was explained above that in Iceland spar there is a particular direction, viz. that of the line joining the two opposite obtuse angles of the natural crystal, in which there is no double refraction, and in which all rays travel with the same velocity. This direction (that is to say, this line and all lines parallel to it) bears the name of the optic axis. There are many other crystals having the same property in one and only one direction, in other words having a single optic axis. There is, moreover, another class of crystals having two such axes. Crystals of the first class or uni-axal crystals are again divided into two groups, viz. positive, in which the extraordinary ray is more refracted than the ordinary, and negative, in which the ordinary ray is the more refracted. It will be remembered that the ray which travels slowest is the most refracted. Among the former may be mentioned

UNI-AXAL CRYSTALS.

Positive.

Apophyllite.	Stannite.
Boracite.	Superacetate of copper and lime.
Ditopaz.	Sulphate of potash and iron.
Hydrate of magnesia.	Tungstate of zinc.
Hyposulphate of lead.	Zircon.
Ice.	
Quartz.	
Red Silver.	

Negative.

Apatite.	Honey stone.
Arseniate of copper.	Idocrase.
Arseniate of lead.	Mellite.
Arseniate of potash.	Mica.
Beryl.	Molybdate of lead.
Carbonate of lime and magnesia.	Nepheline.
	Octaedrite.
Carbonate of lime and iron.	Phosphate of lime.
Chloride of calcium.	Phosphate of lead.
Chloride of strontium.	Rubellite.
Cinnabar.	Ruby.
Corundum.	Sapphire.
Emerald.	

* Continued from p. 386.

Crystals are usually divided into six systems, in each of which there is a fundamental aad a variety of derived forms. The fundamental form of each system is based upon the number, magnitude, and inclination of the crystallographic axes or lines drawn through a point in the interior of the crystal, and terminating in its angles. The optic axes do not of necessity coincide with any of these.

(1.) The regular system, which is based upon a system of three equal rectangular axes. Any form derived from this will be perfectly symmetrical with reference to the three axes, and will present no distinguishing feature in relation to any of them. Crystals belonging to this system have no optic axis, nor any doubly refracting property.

(2.) The quadratic system, based upon a system ot three rectangular axes, whereof two are equal, but the third greater or less than the other two. Crystals belonging to this system have one optic axis coinciding with the last-mentioned crystallographic axis.

(3.) The hexagonal system, having three equal axes lying in one plane inclined at 60° to one another, and a fourth axis at right angles to the other three. Crystals of this system have one optic axis coinciding with the fourth crystallographic axis. Iceland spar belongs to one of the derived forms of this system.

(4.) The rhombic system, having three rectangular but unequal axes.

(5.) The monoclinic system, which differs from the rhombic in this, that one of the three axes is oblique to the other two, which are still rectangular to one another.

(6.) The triclinic system in which all the axes are oblique.

All crystals belonging to the last three systems have two optic axes. In the rhombic system they lie in a plane containing two of the three crystallographic axes; in the monoclinic, they lie either in the plane containing the oblique axes, or in a plane at right angles thereto. In the triclinic no assignable relation between the optic and the crystallographic axes has been determined.

The phenomena of colours and their variations hitherto described have been produced by a beam of light, all the rays of which were parallel in their passage through the crystal or other substance under examination. There is, however, another class of phenomena due to the transmission of a convergent or divergent beam of polarised light, which we now proceed to consider.

It was shown above that the retardation due to any doubly refracting crystal, and consequently the colour produced by it is dependent on the thickness; and that with a crystal of constantly increasing thickness, the colours go through a complete cycle, and then begin again. Suppose then a divergent beam to fall perpendicularly upon a uni-axal crystal plate cut at right angles to the optic axis; the central rays will fall perpendicularly to the surface; but the rays which form conical shells about that central ray will fall obliquely. The rays forming each shell will fall with the same degree of obliquity on different sides of the central ray, those forming the outer shells having greater obliquity than the inner. Now the more obliquely any ray falls upon the surface the greater will be the thickness of the crystal which it traverses; and this will still be the case even though it suffers refraction, or bending towards the perpendicular on entering the crystal. Each incident cone of rays will consequently still form a cone when refracted within the crystal, although less divergent than at incidence, in its passage through the plate; and the successive refracted cones will be more and more oblique, as were the incident cones, but in a less degree, as we pass from the more central to the more external members of the assemblage forming the beam of light.

Let A B C D (Fig. 21) represent the crystal plate, O P the

direction of the optic axis and of the central ray, O n, O n′ those of any two other rays. The ray O P will not be divided; but O n will be separated by the double refraction of the plate into two, n s, n r, the one ordinary, the other extraordinary; and these will emerge parallel to one another, and may be represented by the lines s t, r v. Similarly the effect of double refraction on O n′ may be represented by n′ s′, n′ r′, s′ t′, r′ v′. Suppose now that the process were reversed, and that two monochromatic rays, one ordinary, the other extraordinary, reach the plate at s and r in the directions t s, v r, respectively; these would meet at n and travel together to O. Suppose, further, that the difference in length of s n and r n is equal to one wave-length, then, since one of them is an ordinary and the other an extraordinary ray, their vibrations will be perpendicular to one another, and if the polariser and analyser be crossed, the point n viewed from O will appear dark. Similarly, if two rays arrive in the directions t′ s′, v′ r′, at the points s′ r′ respectively, they will meet at n′ and proceed together to O; and if the difference of the paths s′ n′, r′ n′ be two wave-lengths, the point n′ will also appear dark. A pair of rays reaching the crystal at points between the pairs before-mentioned, will emerge at a point n″ between n and n′, and will present a difference of phase equal to a half wave-length. On principles explained in an earlier part of these lectures, such a point n″ will appear bright. On either side of n″, that is towards n and n′, the light will gradually fade. The same alternations of light and darkness will recur at intervals as we proceed along any straight line drawn outwards from the central ray. And inasmuch as the obliquity of the ray is the same for every point equidistant from the centre O, it follows that the phenomena of light and darkness will be the same throughout each circle drawn about the centre O. In other words, the centre will be surrounded by rings alternately bright and dark. The diameters of the ring depend, as was seen above, on the wave-length of the particular light used, and will consequently be different for different coloured rays. If, therefore, white light be used, the different coloured rings would not coincide, but would be disposed in recurring series as we proceed outwards from the centre.

Another effect would, however, also be produced. Suppose the polariser and analyser to be so placed that, the field being regarded as a map, the vibrations in the one being E. and W., those in the other N. and S.; then of the two rays emerging at the most northern or the most southern point of any ring the vibrations of one would be towards the axis, or N. and S.; those of the other would be across it, or E. and W. And of these one would be extinguished by the polariser, the other by the analyser; and the same will be the case for every ring. Hence, throughout a N. and S. line crossing the entire field the light will be extinguished; and a similar effect will obviously occur along an E and a W. line. Hence, when the polariser and analyser are crossed, the entire system of rings will be intersected by a black cross, two of whose arms are parallel to the plane of vibration of the polariser and two to that of the analyser, and the rings in the quadrants on each side of an arm are of complementary tints. When the analyser is turned round through a right angle from its former position, only one set of vibrations (say those executed in a direction E. and W.) will be extinguished, and consequently along one pair of arms of the cross the ordinary rays will pass undisturbed, along the other the extraordinary; that is to say, the cross will be white. When the polariser and analyser occupy any other position than those noticed above, there are two crosses inclined at an angle equal to that between the planes of vibration, each arm of which separates complementary rings.

Various forms of polariscopes have been devised for showing the crystal rings. The simplest of these is the tourmalin forceps, which consists of two plates of tourmalin fixed in cork discs; the latter are encircled in wire in such a way that they may be turned round in their own planes. The wire after encircling one disc is bent round so as to form a handle; it then encircles the other; and the elasticity of the wire allows the pair of discs to be opened and shut like a pair of pincers. If a crystal plate be inserted between the two, and the whole held close to the eye, the rays from parts of the field at different distances from the centre will reach the eye, having traversed the crystal with different degrees of obliquity; and a system of rings and brushes will be formed.

Another method consists in applying to Norremberg's polariscope a pair of lenses, one below the crystal with the crystal in the focus, the other above it. The first ensures that the rays shall traverse the crystal with different degrees of obliquity; the second brings within the range of vision rays which would otherwise fail to reach the eye, and at the same time converging them into a cone with a smaller vertical range, renders the ring smaller than when seen with the simple tourmalins. An additional lens of greater focal length, *i.e.* of less power, is

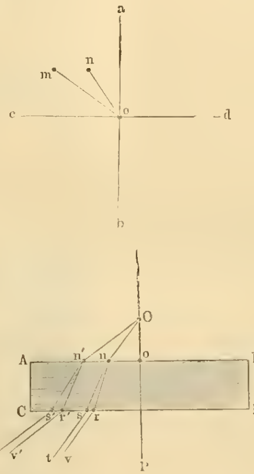

FIG. 21.

often added in order to adjust the whole to individual eyesight.

Fig. 22 gives the general appearance of the addition to the apparatus of Norremberg described above, and Fig. 23 the course of a system of rays brought to a focus on the lens a b, and again converged by a second lens c d.

But by far the most successful arrangement for enlarging the field of view so as to comprise the complete system of rings even with bi-axal crystals having widely inclined optic axes, is the system of lenses due in the first instance to Norremberg. The disposition of the parts is shown in Fig. 24; and the general appearance of the instrument as constructed by Hofmann of Paris, and called by him the "Polarimicroscope," is also given, Fig. 25. In this instrument the lenses which converge the rays upon the crystal plate can be taken out, and replaced by others giving parallel light; it can then be used as an ordinary polariscope.

Mention has been made above of the effect of the circular polarisation of quartz in the colours produced by a beam of parallel rays of polarised light. It remains for us to examine the modification which the rings and

brushes undergo from the same cause. It has been explained that a ray of plane-polarised light in traversing a crystal of quartz in the direction of its axis is divided into two, the vibrations of which are circular, one right-handed, the other left. If the ray traverses the crystal in a direction perpendicular to the axis, and if the original vibrations are neither parallel nor perpendicular to the axis it is also divided into two, whereof the vibrations are not circular but rectilinear. It was suggested, first by Sir G. Airy, that these circular and rectilinear vibrations are limiting cases of elliptical; and both theory and experiment tend to confirm the suggestion, by showing that if the ray be incident on the crystal in any direction

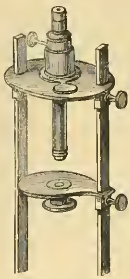

Fig. 22.

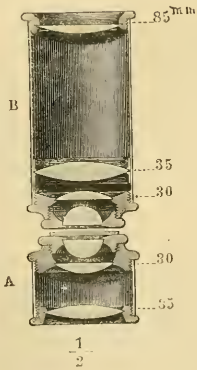

Fig. 24.

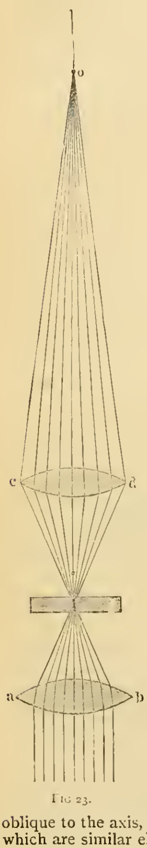

Fig. 23.

oblique to the axis, it is divided into two, the vibrations of which are similar ellipses having the longer diameter of the disc coincident with the shorter of the other, and the motion in the two oppositely directed. The longer diameters of the ellipses coincide with the directions of vibration of the ordinary and extraordinary rays in the case of an ordinary positives crystal; and are consequently directed, the one toward the centre of the figure, the other in a direction at right angles to the first.

The exact, or even appproximate determination of the figures produced is a complicated question, and requires mathematical analysis for its solution, but a general idea of their nature may nevertheless be easily formed. When the polariser and analyser are either parallel or crossed, circular rings are formed, and towards the outer parts of the field traces of the black cross are seen, which grow stronger as we proceed outwards from the centre, that is, towards the parts where the rays are more oblique, and where the polarisation more nearly approaches to rectilinear. But in the centre, and near to it, where the polarisation is circular, or nearly so, the effects will resemble those produced by parallel rays, viz. the rays of different colours will emerge plane-polarised in different planes, and will be variously affected by the angle between polariser and analyser. In no position can they all be extinguished, and consequently in the centre all traces of the black cross will disappear.

When the planes of vibration of the polariser and the analyser are inclined at any other angle than 0° or 90°, the arms of the cross are less strongly marked, and the curvature of the rings becomes less uniform, increasing in the four points where they are crossed by the arms, and diminishing in the intermediate quadrants. When the angle between the planes of vibration is 45°, the rings assume a nearly square form, the corners of the square lying upon the lines which bisect internally and externally the angles between the planes. If the figures are produced

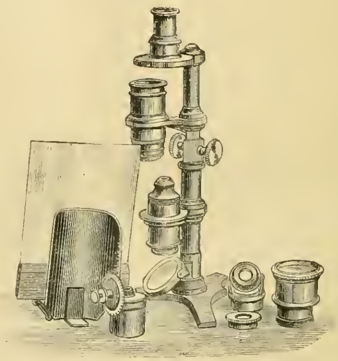

Fig. 25.

with the analyser at 45° by two quartz plates of equal thicknesses, one right-handed, the other left, it will be found that the diagonals of the squares are at right angles to one another, the remains of the black cross occupying the same position in the field in both cases.

If two plates of the same thickness, the one right-handed and the other left, are placed one over the other, a beautiful effect, called from their discoverer Airy's spirals, is produced. In the centre of the field the rotatory powers of the plates neutralise one another, and a black cross commences. As we proceed outwards, the arms of the cross cease to be black, and become tinged with red on one side, and with blue on the other. At the same time they are bent round in a spiral form, in the direction of the hands of a watch if the first plate be right-handed, and in the opposite direction if the first plate be left-handed. These spirals intersect at intervals the circular rings; the points of intersection lie in four rectangular directions, which terminate towards the outer margin of the field in four arms of a shadowy cross. The colours of the rings and spirals are more brilliant and better defined than in most other phenomena of chromatic polarisation.

W. Spottiswoode

(To be continued.)

REPORT OF PROF. PARKER'S HUNTERIAN LECTURES "ON THE STRUCTURE AND DEVELOPMENT OF THE VERTEBRATE SKULL" *

II.

IT is well known that the eggs of sharks and rays, when deposited, are enclosed in a strong horny capsule or "purse" formed as a secretion from the oviduct. In both groups these curious appendages have the form of a pillow-case, the corners being pointed in the rays, and produced into long tendril-like processes in the shark and dog-fish. The embryo remains enclosed in the purse until about six months after oviposition, and it is during this period that all the most important metamorphoses are gone through.

The youngest embryo described was nearly an inch

Fig. 3

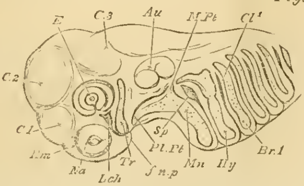

FIG. 3.—Head of Embryo Dog-fish, 11 lines long. Lch, lachrymal cleft; C 1, 2, 3, Cerebral vesicles; Hm, Cerebral hemispheres; fnp, fronto-nasal process; Sp, Spiracle. Other references as before. The visceral arches are dotted for distinction's sake.

long, an extremely active little creature, attached to a yolk-sac about $\frac{3}{4}$ of an inch in diameter. In this stage the head and branchial region are large and conspicuous, the body slender, and tapering off to a long thread-like tail. The dorsal laminæ have completely united, leaving, however, a very thin covering to the hinder division of the brain, which consists of the three primary cerebral vesicles (Fig. 3, C 1—3), bent over the end of the notochord in such a way that the second, or middle division, forms the anterior termination of the head; the "cerebral flexure" is, therefore, complete. The future hemispheres (Hm) have already appeared as small buds from the fore-

Fig. 4

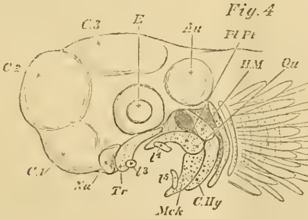

FIG. 4.—Head of Embryo Dog-fish, $1\frac{1}{6}$ in. long. References as before.

brain (C 1). The nasal, visual, and auditory organs are in an extremely rudimentary condition. On the under surface of the head is the large square mouth, bounded above by the fronto-nasal process (fnp), a shield-shaped elevation of the integument between the nasal sacs, found in the embryos of even the highest vertebrata, but persistent in the sharks and rays. Beneath the eye, and communicating by a slit running below the inferior boundary of the fronto-nasal process, is a cleft (Lch) answering to the lachrymal passage of the higher vertebrata, and formed by the shutting off of a portion of the original first visceral cleft by the growth of the pterygo-palatine arcade. This cleft, persistent in the higher animals, is a transient structure in the Elamobanchs. One of the most noticeable features in the embryo at this stage is the presence of a number of long filamentous external gills, each containing a single capillary loop; of these about ten spring from the hyoid and each of the branchial arches, while four much shorter ones project from the future spiracle, and are attached to the mandibular arch. The internal branchiæ are at present functionless, and form mere cog-like projections on the arches.

The embryo at this age is so transparent, that the visceral arches can be seen with sufficient distinctness through the skin without any dissection whatever. Even at such an early period, the anterior face-bars already begin to show signs of segmentation, there being constric-

Fig. 5.

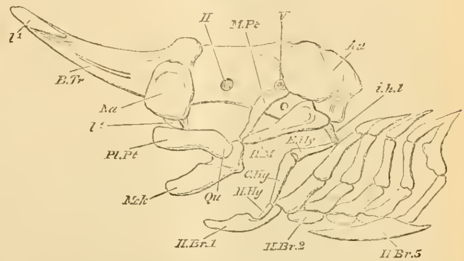

FIG. 5.—Skull of Ray. M Pt, Spiracular cartilage; ihl, inter-hyal ligament.

tions in the mandibular and hyoid arches, where division will afterwards take place. The upper part of these arches has assumed the pedate form which is taken on at a later period by the branchials. The pterygo-palatine arcade is already as large proportionally as in the adult, the true apex of the mandibular arch being reduced by its outgrowth to a mere tubercle (M Pt).

Granular subcutaneous thickenings have already appeared in relation with the face-bars; these are the extra-viscerals. In the same unchondrified condition are the parachordal and paraneural elements of the skull.

Embryos of $1\frac{1}{6}$ and $1\frac{1}{2}$ in. in length possess external gills

Fig. 6

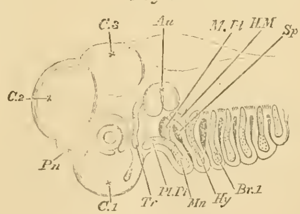

FIG. 6.—Head of Embryo Ray, $1\frac{1}{2}$ in long. Pn, Pineal gland.

two or three times as long as in the preceding stage those on the mandibular arch having already shrunk and begun to form the pseudo-branchia; the internal gills are still functionless. The eye is completely formed. The investing mass and the nose and ear capsules are chrondified, but the two halves of the former are still separate, and the roof and walls of the cranium membranous. To make out clearly the relations of the facial arches, it is now necessary to dissect away the skin (see Fig. 4); it is then seen that the process of segmentation has advanced greatly, the arches behind the mouth being split up as in the adult, and differing from those of the full-grown shark only in form. The trabeculæ have become flat-

* Continued from p. 426.

tened out from above downwards, but are still separate, and the lower-jaw arch, besides being divided into paleto-quadrate and Meckel's cartilage, has approached still more nearly to the adult character by the conversion into fibrous tissue of its apex (Figs. 2 and 3, M Pt).

The third stage described was a ripe embryo, about two inches long, having nearly the form of the adult. In this condition the external gills have entirely disappeared, the internal gills now performing the whole function of respiration. The skull has assumed all the characters of the adult, except as regards a few minor details, chondrification and segmentation being perfect. The investing mass has not only completely enclosed the notochord, but has formed an arch, like that of a vertebra, over the hinder part of the brain : in this way the occipital region of the skull is formed. The roof and walls of the brain-case, membranous in the last stage, have now become cartilaginous, and are fused with the nasal sacs in front, the trabeculæ below, and the auditory capsules and occipital region behind. The trabeculæ form the whole of the flat skull-floor in front of the ear capsules, where their original apices (pharyngo-trabeculars) are still to be seen as small rounded processes; they have completely coalesced behind, but are merely in apposition between the nasal sacs. The basi-trabecular (Fig. 2, B Tr) is small, and the first pair of labials (l^1), which together with it form the "cutwater," are flat, and widely separated; the snout is consequently much blunter than in the adult. The hypo-trabeculars (cornua trabeculæ of Rathke) occur as two inturned S-shaped filaments of cartilage on either side of the basi-trabecular : no trace of them is to be found in the adult.

III.—*Skull of the Ray or Thornback* (Raia clavata).—On the whole the skull of the ray resembles very closely that of the shark ; in some respects, however, it approaches more nearly to the higher fishes, and in others, again, retains a lower or more embryonic character.

One of the chief points of difference between this type and the preceding is the much greater elongation of the skull, chiefly owing to the immense development of the basi-trabecular (Fig. 5, B Tr), which is produced to form the long, stout rostrum, the apex of which is strengthened by the first pair of labial cartilages (l^1). The region between the orbits is much pinched in, while the nasal and auditory regions are extremely broad, the nose capsules, especially, being as far apart as in the embryo shark. On the upper surface, the prominences (epiotic, pterotic, sphenotic) already described in the shark, are seen ; but instead of one, there are two fontanelles, an oval one between the nasal sacs, and a second of an oblong shape, in the more normal position, between the orbits. On the under surface of the nasal capsules are seen the second, third, and fourth labials, forming a valvular apparatus for the nostrils ; the fifth labial and the extra-branchials are absent.

The upper and lower jaws or dentigerous arches closely resemble those of the shark ; the opening of the mouth is, however more completely on the under surface of the head, as in the embryo Squaloid. In the front wall of the spiracle a semi-lunar cartilage (M Pt) is found, connected by ligament with the auditory capsule above, and with the angle of the lower jaw below, and having the same relations to the fifth and seventh nerves as the metapterygoid ligament of the shark (Fig. 2, M Pt), or the bone of the same name in the osseous fish ; this, therefore, is the true apex of the mandibular or first post-oral arch.

There is no mistaking the hyo-mandibular (H M) a cartilage having precisely the same connection and relation to the hinder division of the *portio dura* as the part similarly named in the shark, but much more slender, pointed below, and inclined forwards. The remainder of the hyoid arch, however, has taken on an entirely new character, and shows a marked advance towards the Teleostian type, being attached, not to the lower part of the hyo-mandibular, but to its upper posterior angle, by means of a band of ligamentous fibre, answering to the small styliform bone (stylo-hyal of Cuvier) which in the osseous fish connects the free portion of the hyoid with the suspensory apparatus. The gill-bearing part of the hyoid is slenderer than in the shark, and more highly segmented, being divisible into epi- cerato-, and hypo-hyals (E Hy, C Hy, H Hy) ; the basi-hyal or keystone-piece is absent.

The branchial arches differ from those of the shark chiefly in the great development of the inferior segment or hypo-branchial. The first of these (H Br. 1) is much extended, and, uniting with its fellow of the opposite side, forms a transverse bar behind Meckel's cartilage. The second, third, and fourth hypo-branchials are broad adze-shaped plates, while the fifth is coalesced with its fellow in its hinder half, and extended forwards, so as nearly to meet the corresponding piece of the first arch.

The youngest ray described was an embryo of *R. maculata*, $1\frac{1}{3}$ inch long, taken from the purse at about the seventh week from oviposition. The body proper is not larger than that of the first stage of the dog-fish, the greater length being due to the immense development of the tail. The pectoral fins, which by their expansion and union in front with the head, give to the adult ray its peculiar depressed form, are at this age small semi-elliptical lobes, one on each side of the umbilicus or point of attachment of the large yolk-sac. Six or seven long branchial filaments, expanded or spatulate at the end, are attached to the hyoid and branchial arches, but none are apparent externally on the mandibular.

The facial arches are visible in a side view with perfect distinctness, and have already advanced considerably in segmentation, the apex of the mandibular being on the point of separation so as to form the spiracular cartilage, and the proximal end of the hyoid being cleft vertically, thus separating the hyo-mandibular from the epi-hyal.

Three months after oviposition, although the yolk-sac is still as large as a small walnut, the embryo has completely taken on the adult form, the pectoral fins having enlarged greatly, and brought the gill-slits to the ventral surface ; from these the external branchiæ still project, being now in the form of long threads, almost like the hyphæ of a fungus ; the first cleft behind the mouth (tympano-eustachian) remaining on the upper surface has taken on the form of the spiracular opening.

In the skull very few embryonic characteristics are left, the chief being that the brain-case is rounder, the rostrum shorter, and the two first labials separated from it by a slight interval, instead of being in perfect apposition.

METEOROLOGY OF THE WEST INDIES

THE hurricane season, here reckoned from July 25 to October 25, went by without damage so far as the Windward and Virgin Islands are concerned, though not without disastrous examples of the phenomenon from which it derives its name elsewhere. Two cyclones of the ordinary kind have in fact visited these seas during the above period ; and although neither of them included the island of St. Thomas in its range, yet they passed sufficiently near to make us aware of their existence, and to create considerable alarm among the inhabitants.

The first of these appears to have originated about lat. 10° N. long. 55° W., on or near August 10. Taking a north-westerly direction it passed parallel with, but at a considerable distance from the Windward islands, where from August 11 to 13 the weather showed signs of great disturbance with violent squalls, that shifted to every part of the compass ; while at Martinique in particular, where

the most threatening signs appeared, the mercurial barometer sank to 29·60. On the 14th similar indications showed themselves at St. Thomas—rain, squalls, and thunder; while on the night of the 15th the barometer suddenly fell to 29·70, and a violent gust of wind from the north caused many of the natives to barricade their windows in anticipation of the worst. This state of things lasted till next day at noon, when the mercury rose and the sky cleared.

But by this time the cyclone, now only about a hundred miles to the east of the islands, had fully formed itself; and henceforth its course was only too clearly marked by the damage it caused among the shipping. From August 17 to 24 it passed north, with a westerly inclination, till it fell in with the course of the Gulf Stream, above Florida, and then followed that line, but gradually nearing the coast, up to Nova Scotia, where the ravage was tremendous, upwards of a hundred vessels having been either dismasted, or rendered total wrecks. Further north the cyclone seems to have expanded into an ordinary storm and disappeared.

These particulars I gathered from the captains of the injured vessels, some of which took refuge in this port. They are illiterate men, and not capable of furnishing exact details; but all agreed in describing the wind-current as having been from north to south by west, and so back by east to north; the lowest barometric indication I heard speak of was 29°.

The second cyclone originated in the Carribæan Sea itself, to the west of Barbadoes. Telegrams of threatening weather dated September 25 reached us at St. Thomas; and on the 26th the aspect of matters here was gloomy; the sky murky, especially to the south, with continued flashes of lightning, and a very heavy sea. But the hurricane did not touch Santa Cruz; its first long-shore visit having been made on the 28th at Haiti, where several small ships were lost, and much mischief done. Jamaica escaped; but on the 30th the whole southern coast of Cuba was ravaged from east to west, and many lives lost by sea and shore. From Cuba the cyclone continued to pass west till it reached the Mexican coast, which it skirted, then turned east, touching Havanna on October 4, Florida on the 7th, and then, following the Gulf Stream, was lost in mid-ocean. Its greatest fury was in the Gulf of Mexico itself, where the injury done to the shipping almost equalled that caused off Halifax by the gale of August 24.

Some disquietude has also been caused here at St. Thomas by the frequency of slight earthquake shocks, of which I counted five within a period of forty days. The two strongest occurred on July 22 and August 12; in both instances the movement appeared to pass from east to west; it was accompanied by a distinct rumbling sound. The shock of August 12 occurred at 8.15 P.M., and was within a few seconds followed by another, but slighter. In two instances, June 16 and August 27, a slight shock at this island had been preceded, about an hour and a half before, by a stronger one at Jamaica: so that the general direction of the movement must have been contrary to the apparent surface vibration from west to east.

I may add that the whole of this island is manifestly undergoing a gradual upheaval, as appears by the wave-worn rocks of recent date, but already two or three feet above water mark; sea-shells and corals left dry, and similar indications. Hence the artificial channel opened, for purposes of cleansing by means of the current thus established, between the south-western extremity of the harbour and the outer sea, and which is in itself a clean cut, twenty feet wide, through a narrow band of rock, has, since 1870, when it first was made, lost so much of its depth as scarcely to allow of boat-passage; and threatens at no distant period to become absolutely useless.

W. G. PALGRAVE

NOTES

THE well-known German serial, Poggendorff's *Annalen der Physik und Chemie* has now been in existence fifty years, and we are glad to see that practical recognition has just been taken of the striking fact that it has, during this long period, been under the sole editorial direction of Prof. Poggendorff, while printed and published by the same house in Leipzic. It was agreed, a short time since, by a number of friends of the learned professor, that they should relieve him of his editorial duties for one volume, and that this should be presented to him in honour of the occasion, as a "Jubelband," or Jubilee volume. The importance of the work done by M. Poggendorff and his *collaborateurs*, during half a century, through the *Annalen*, is sufficiently obvious to any who have taken an interest in the progress of physical science in recent years. The serial well reflects that enterprise, plodding industry, and philosophical insight, which mark original research in Germany; and the 156 volumes that have appeared (six of these supplementary) constitute an invaluable storehouse for any one desiring to prosecute new lines of investigation in the wide field of physics. We learn from the preface to the Jubilee volume (which we hope to notice at greater length) that the entire number of papers published in the *Annalen* hitherto is 8,850; and among the 2,167 authors who have contributed to its pages, we find the eminent names of Liebig, Magnus, Berzelius, Rammelsberg, Rose, Faraday, Brewster, Becquerel, Regnault, and many others. A work of this kind, as is truly remarked, unites those engaged in similar researches all over the world, into one large brotherhood of mutual assistance and regard. We congratulate the learned editor on the completion of such a long term of arduous and honourable service to Science, and heartily join in the wish that this Jubilee volume may be followed by many others edited by the "Jubilar" himself.

WE are given to understand that preliminary negotiations are on foot for the establishment of a central establishment for Ocean Meteorology in Germany. We may hope that when such a step is in contemplation, the work done by Herr von Freeden, who has for the last seven years conducted the Norddeutsche, lately called the Deutsche, Seewarte, at Hamburg, will meet with its full measure of recognition. The establishment in question has been maintained at the sole expense of the town of Hamburg, and has risen steadily from a small beginning to its present state of thorough efficiency, thanks, in great measure, to the energy of its director.

IN the review of Belt's "Naturalist in Nicaragua" by Mr. Wallace, p. 221, reference is made to the theory of the origin of cyclones propounded by the author in terms which might lead our readers to think that his views have been entirely unnoticed. Such is however not the case, and our attention has been drawn to Prof. Reye's work "Die Wirbelstürme, &c., in der Erd-Atmosphäre, mit Berücksichtigung der Stürme in der Sonnen-Atmosphäre" (Hanover 1872), in which Mr. Belt's views are discussed at some length, with an expression of regret that so little attention has been attracted to them.

THE Turners' Company of the City of London have acknowledged the debt which their Art owes to pure scientific research, by presenting the freedom and livery of that Company to Dr. John Phillips, F.R.S., Professor of Geology in the University of Oxford, in recognition of his introduction into architecture of the various materials which constitute the rocks of England. Mr. John Jones, a member of the livery, said the City of London was always willing to bestow its honours on successful generals, conspicuous statesmen, and devoted patriots—and the tributes were honourable to both sides—but that was the very first occasion on which they had offered

the like distinction to a patient, observant, and reflecting student of nature. In doing so they, at the same time, offered their thanks to the University of Oxford for having included physical science in its curriculum of education, and they celebrated, so to speak, the alliance in that city of art and science.

THE recent appearance of a French translation of the last edition of Prof. Haeckel's world-known "Natürliche Schöpfungs-Geschichte;" or, "History of the Creation of Organised Beings," will give a larger number of students the opportunity of mastering its valuable contents. How is it that no translation has yet appeared in our own language?

MEN of Science will be glad to learn that the Premier has recommended to the Queen for a pension of 100*l.* on the Civil List Mrs. C. L. Basevi, the mother of Captain Basevi, who lost his life on the Thibet frontier of India, whilst engaged in exploring the mountain passes, and pursuing other scientific inquiries.

DR. JOHN ANDERSON, Director of the India Museum of Calcutta, is at present in this country on two years' leave of absence. He is, however, devoting his holiday to working out the results of the Yunan Expedition, to which he was attached as naturalist three years ago. The Linnean Society has undertaken their publication, which will embrace a full description of the anatomy of the fresh-watar Dolphin of the Ganges (*Platanista gangetica*), as also of the still rarer fresh-water Cetacean of the Irawady *Orcella flumenalis.*

ON Friday, April 10, M. Leverrier gave a *soirée* at the National Observatory of Paris, in honour of the delegates of the French Scientific Societies. The weather was unfavourable, but the exhibition of scientific instruments was very successful indeed. Many new electrical apparatus were exhibited for the first time. No gaslight was used; an electrical lamp by Perrin being the only lighting medium. A lecture was delivered by M. Wolf, on phenomena of polarisation, illustrated by optical experiments by Dubosc.

THE Commissioners for the Construction of a Universal Metre are at present superintending the fabrication of the definitive standards, which will be distributed amongst the several Government delegates to the International Congress. The operations are executed at Paris, in the laboratory of the School of Mines.

M. ALLUARD, the originator and director of the Puy de Dome Observatory, has announced that an inauguration will take place next September. Invitations will be sent to England as well as throughout France. The cost of the building will be something more than 4,000*l.*, and the work is fast advancing. The Puy de Dome Observatory will be connected by an electric telegraph with another observatory built at Clermont, and which is already in operation; the difference of level between the two stations will be more than 4,000 ft. When excavating on the top of the mountain it was discovered that a large building about 80 yards in breadth had existed on the spot. It is supposed to have been a Roman fortress and temple; a number of Roman medals were discovered.

M. COLLADON, the Geneva physicist, has published an essay on the subject of turning poplars into lightning conductors. He proposes to insert in the lower part of the trunk a metallic rod, which he connects with the earth by a chain, so that the fluid cannot leave the tree to dart at any object placed within a short distance, which at present is very often the case.

M. SAINTE-CLAIRE DEVILLE, appears to have been again successful in his weather predictions. We shall give details in our next on the important question.

FRENCH officials are organising a fusion between the postal and telegraphic officials.

A REMARKABLE instance of the rapid spread of a new pest is furnished by the history of *Puccinia Malvacearum*, a fungus parasitic on various plants belonging to the natural order Malvaceæ. Its native country is probably Chili, where it was discovered by Bertero on *Althæa officinalis*. Its first appearance in Europe was in April 1873, on *Malva sylvestris*, in the neighbourhood of Bordeaux, and in August it had extended to several other plants of the same order in the botanic gardens of that town, but, singularly enough, was not found on *Althæa officinalis*, several other nearly allied genera being also exempt from its attacks. In Germany it was first discovered in October, while in this country it was detected in the summer of 1873, nearly simultaneously in many widely-dispersed localities, as Exeter, Salisbury, Chichester, Shere in Surrey, the neighbourhood of London, Eastbourne, Pevensey, Sandown in the Isle of Wight, and Lynn, and threatens to be exceedingly destructive to the hollyhocks.

TWO remarkable instances of protective mimicry have lately been described by Prof. Gerstaecker, both among parasitic Hymenoptera, and having apparently for their object to facilitate the access of the parasite to the nest of the host for the purpose of laying its eggs. *Crypturus argiolus* differs altogether in colour and marking from the allied species of Ichneumonidæ, and assumes even in the minutest details those of the wasp *Pollistes gallica*, on which it is parasitic. To so great an extent is the mimicry carried out that even variations characteristic of particular districts are reproduced, the area of distribution of both insects being very wide. In the second case it is the colour and markings of a wasp, *Vespa germanica*, that are imitated by its parasite *Conops diadematus*.

AT the east end of the Palm House at Kew there is a fine specimen of the rare *Agave univittata* coming into flower. Near it stand the still stately flowering stems of two allied plants, *Agave jacquiniana* and *Fourcroya gigantea*.

THE French conscription enables us to study annually the composition of the growing generation. Last year from about 300,000 young men passing the examination for recruiting the army, 16,000 were discharged on account of having lost their brothers or having had them wounded in the war, 11,400 as being sons or grandsons of widows, or of people above seventy years of age, 1,600 elder brothers of orphans, 16,000 as not being strong enough, 10,000 for lameness, 8,000 not tall enough, 4,000 from having defects of the bowels, 3,000 of the eyes, 2,700 organs of generation, 2,000 bad teeth, 1,000 as being mute, &c., 1,200 epileptics, 600 deaf, 80 blind, 1,000 phthisic, &c.; in all, 89,000 were left out of the contingent.

IN the report furnished us by the Secretary of the Anthropological Institute (vol. ix. p. 345) of Mr. Distant's paper On the Mental Differences between the Sexes, the author is said to have referred to the "now moderately well established fact that in primitive races the *hair* of women approximates more closely to that of man than obtains in a higher state of civilisation." Mr. Distant in his paper referred to the *brain*, not to the *hair*.

A QUICKSILVER mine is said to have been discovered at Exeter.

M. GASTON TISSANDIER is publishing at Hachette's an excellent popular work on "Photography," with numerous illustrations. One of them shows Charles, the inventor of the gas balloon, photographing the silhouette of one of his pupils on a paper sensitised with one of the salts of silver, more than twenty years before the discovery of Daguerre.

IN his recent paper On the Placentation of the Sloths, published in the Transactions of the Royal Society of Edinburgh, Prof. Turner has done much to diminish the value of placental charac-

ters in the classification of the higher mammalia. In *Cholœpus hoffmanni* the placenta is dome-like, multilobate and genuinely deciduate, more like that found in the Primates and Man than in any other order, so much so that the author remarks "from the point of view of the descent hypothesis, it is possible that between the Sloths and the Lemurs genealogical relations may exist," and "now that I have called attention to the evidence of affinity with these higher mammals it is not improbable that other features of resemblance may in time be recognised."

BESIDES the ornithological papers which the late Mr. H. D. Graham contributed to the *Naturalist*, he left in the form of manuscript notes the larger and more interesting portion of the ornithological work which he had undertaken in the islands of Iona and Mull during the latter part of his life. These, together with the papers referred to, are being prepared for publication by Mr. R. Graham, to whom the whole of Mr. Graham's ornithological correspondence was originally addressed.

WE learn from the *Times* that M. Giard, Professor of Natural History at Lille, has been making an interesting inquiry into the zoology of the French shore of the Straits of Dover. Many uncommon species of crustaceans, ascidians, and mollusca have been obtained, which will be fully described before the Scientific Congress which is to be held at Lille during the ensuing summer.

WE are glad to see that Government have at last begun to carry out their agreement with the Trustees of the Bethnal Green Museum, by laying out the vacant space around the Museum in gardens for the recreation of the people.

IN the House of Commons, on Tuesday, Mr. Cowper-Temple obtained leave to bring in a Bill to remove doubts as to the powers of the University of Scotland to admit women as students, and to grant degrees to women.

THE month of April is a famous one in the annals of the French Academy for centenary anniversaries. M. Biot was born in April 1774, almost the same day when Louis XIV. died. M. Biot was a member of the Academy of Sciences and Academy of Inscriptions. It was also in this month that Maupertuis published the first French mathematical essay in which the Newtonian theory of attraction was accepted. Lavoisier was engaged in making observations on solar heat with an immense lens at the cost of one of the richest financiers of the time.

THE last (received) number of *Annales Hydrographiques*, contains details of the navigation of the Magellan Straits by the corvette *L'Atalante*, with tabulated meteorological observations made during the 13 days of the passage.

THE continuation of Adolph Schaubach's "Deutschen Alpen" (pp. 641 to 850) is brought up to the end of the Trias. The writer is Dr. H. Emmrich.

THE last number of the *Annales des Sciences Géologiques* contains a continuation of M. Oustalet's researches on the fossil insects of the Tertiaries of France. This second instalment of 112 pages is devoted to Aix-en-Provence.

THE recently published Report of the Department of Mines of Nova Scotia shows that the total produce during the year from collieries was 1,051,467 tons. Of these 264,000 tons were sold to the United States, 6,000 to Great Britain, 214,000 were used in Nova Scotia, and the rest were sold to Quebec, New Brunswick, Newfoundland, Prince Edward Island, West Indies, and South America.

A STAINED glass window has just been placed in the parish church of Folkestone to the memory of Dr. William Harvey, the discoverer of the circulation of the blood, who was born in the town in 1578. It is the gift of the medical profession, more than 3,000 of whom have contributed towards the cost.

IN view of the great economical value of the fur seals of Alaska, and of the importance of a thorough knowledge of their habits and movements, with reference to the command of the market of the world, it is proposed by the United States Treasury Department to send some one to the North Pacific Ocean for the purpose of obtaining materials for an exhaustive report on the subject. It will be remembered that these seals, almost to the number of millions, visit the St. George and St. Paul islands of the Pribylov group every summer season for the purpose of bringing forth their young, and that on this occasion a company chartered by the United States is allowed to capture 100,000 annually. What becomes of these seals after they leave the islands is entirely unknown, although congregated there in such numbers for several months. A few are taken in the spring and fall as they pass along the coast of British Columbia and Washington Territory, but whether these are related to the Pribylov army or not is uncertain. The same species is found to a limited extent on the Asiatic side of the ocean, but no very extensive captures are made. Should this commission be appointed, it is to be hoped that some of these problems may be solved, and that we may not remain longer in ignorance of the general natural history of so important an animal, which furnishes a revenue to the United States of about 300,000 dols. a year, while a profit of almost millions is made by the company which has charge of the interest.

THE additions to the Zoological Society's Gardens during the last week include a Vigne's Sheep (*Ovis vignei*), from Asia, presented by Capt. Archibald; a Sambur Deer (*Cervus aristotelis*) and an Axis Deer (*Cervus axis*), from India, presented by the Hon. Justice Jackson; two Cut-throat Finches (*Amadina fasciatus*) and two Paradise Whydah Birds (*Vidua paradisea*) from West Africa, presented by Lieut. J. H. Hearne, R.N.; a Rufous-necked Weaver Bird (*Hyphantornis textor*) from West Africa, presented by Mr. Hincks; two Negro Tamarins (*Midas ursulus*) from Rio de Janeiro; a Common Rhea (*Rhea americana*) from Buenos Ayres; a Brazilian Teal (*Querquedula brasiliensis*), and a Bahama Duck (*Pœcilonetta bahamensis*) from South America, purchased.

THE PHYSICAL HISTORY OF THE RHINE*

THE attempt to unravel geological history, as far as the stratified rocks are concerned, and all the igneous rocks connected with them, simply resolves itself into this:—an effort to realise the physical geography of different geological epochs, to make out the relations of the sea and of the land with its plains and mountains during these periods, the history of the rivers and lakes of the time, and to know as much as may be known of all the creatures and of all the vegetation which inhabited the water and the land.

I am now going to attempt to explain the history of that great historical river the Rhine. Every river has a definite history, if we could clearly make it out. Every river has had a beginning, and it is quite possible—if we have the skill—to find out when, by special changes in physical geography, such and such a river began to flow, and why it flows in such and such a direction.

In various publications I have attempted to show what is the history of some of the rivers of England; as, for example, the history of the Severn and of the Thames, and I think I have been able to prove that the Severn is a much older river than the Thames; and, on similar principles, I now propose to attempt to reveal to you the history of the Rhine and its

* A Lecture delivered at the Royal Institution on Friday evening, March 27, by Prof. A. C. Ramsay, LL.D., V.P.R.S., Director-General of the Geological Survey of the United Kingdom, &c.

valley from early times to the present day. For many years I had an ambition to work out the history of the Rhine. I have known it now for more than twenty years; going often up and down the river, and sometimes for weeks—once for months—living on its banks. For the last thirteen years, unfortunately, I never was able to return to it, but the problem I had marked out for myself remained in my mind, and last year I went, and worked it out, with the result which is now to be explained.

First, with regard to the great main features of the Rhine valley; it has its sources, as every one knows, in the mountain regions of Switzerland, one of which is in the valley of the Vorder Rhine, and the other in that of the Hinter Rhine, both glacier regions. The ground where it rises is from 7,000 to 8,000 feet above the level of the sea. From thence it passes to the Lake of Constance, 1,305 feet above the sea; and beyond, in a westerly direction, by Schaffhaussen to Basel, where, at the bridge, the level of the water has an average height of about 803 feet above the sea. Thence it flows down the great upper plain of the Rhine northerly between the Schwartzwald and the Vosges to Mainz, where the height of the river is about 531 feet above the level of the sea, thus showing a fall between Basel and Mainz of about 272 feet, which gives an average slope for the running of the river of about 3 ft. 1½ in. per mile. Beyond that, proceeding to the north, we come to the deep gorge of the Rhine, passing between high cliffy banks, which begin at Bingen and continue down to Rheineck in the neighbourhood of the Siebengebirge, for a distance of from 60 to 70 miles, according as you take into account all the windings or omit them. Beyond the Siebengebirge there is a plain, partly formed of the delta of the river, which gradually merges into the great flats that extend all the way from Calais to the Elbe.

Now the main question I have to bring before you is, first, what is the origin of the great upper plain that lies between Basel and Mainz? and, secondly, what is the origin of the gorge between Mainz and Rheineck? Why are they there, and by what means have this plain and this gorge assumed their present forms?

When you stand above Bingen, or, better still, if you ascend the Taunus and look southerly, and consider the narrowness of the gorge and the great hilly barrier of rock that must once have extended at Bingen across the lower end of the plain, the impression is irresistibly conveyed to the mind that before that gorge was opened a vast lake must have reached all the way from that barrier to where Basel now stands, covering the great plain that lies between the mountains of the Vosges and those of the Schwartzwald. And so thoroughly has this idea taken possession of the popular mind, at least of those who have at all considered the subject, that we find this statement made in some of the Guide Books of the time, and notably by Baedeker, where it is stated that a lake must have covered the whole of that vast plain, 170 miles in length, at a comparatively recent period. It is a very obvious theory and has much to recommend it, for it seems so clear that, before the gorge was opened, all that plain must have been covered with a sheet of water, and it is hard to realise that such has not been the fact. When I first entered on the subject I was impressed with this idea, and I began to cast about and endeavour to find a reason for the scooping out of the gorge, and for the consequent drainage of the supposed lake.

Having years before written a paper on the origin of the lake basins of Switzerland, North America, and other parts of the world, and having attributed the formation of many of these, but by no means all of them, to the action of glacier-ice during the glacial period, my first impression was that ice might have had at least something to do with the scooping out of the great valley that lies between the north flanks of the Jura, the Schwartzwald, the Vosges, and the Taunus. But while slowly passing up the river, and searching for proofs which might either confirm or contradict this view, I was soon obliged to give up the idea that glacier-ice had anything to do with scooping out the great hollow. For on one side—that of the mountains of the Schwartzwald—I found that none of the glaciers of that region (and there are proofs that glaciers once existed there) even extended well down into the valley of the Rhine. And on the opposite side of the Rhine Valley, that of the old glacier region of the Vosges, I found no proof that they ever extended down so far as the plain. There is also no proof that the glaciers of the great glacial epoch of Switzerland ever extended as far north as Basel. Neither are there any signs of erratic blocks or other kinds of moraine matter on the plains or hill-slopes about Bingen, which one might expect to find there had the whole of the great plain of the Upper Rhine been once filled with glacier-ice. Therefore this theory, which I had not definitely formed, but which I surmised might possibly have had something to do with the subject, entirely melted away, and other hypothetical views along with them, and I was obliged to begin anew.

Accordingly I went to Switzerland, and with the help of friendly Swiss geologists, examined part of the Miocene or Middle Tertiary rocks between the Oberland and the Jura.

To make the rest of the subject clear, I must now say a few words about the origin of mountain chains. Most people are familiar with the outlines of the nebular hypothesis. The whole solar system was once in a nebulous state, and as this nebulous mass revolved in space, portions of it were thrown off, and one of these consisted of the matter which, by and by, resolved itself into the present earth. This nebulous fluid, in virtue of gravity, by degrees condensed more and more, and, passing through what we may call the molten state, in the course of time began to assume a solid form, and a hard outer crust was at length produced which enclosed a highly-heated fluid mass within. This crust, which continued to thicken in consequence of radiation of heat, because of the law of gravitation, was ever drawn towards the centre of the earth. By this process the circumference of the earth necessarily became less, and that consolidated rocky sphere which formed the outer shell of the earth was forced to readjust itself so as to occupy a diminishing area. Thus it happened that while some parts sank, other parts of the crust were crumpled, and relatively raised higher than other portions of the crust that still retained their original curves as part of a sphere.

This hypothesis, which, as far as I know, was first propounded by Elie de Beaumont, may be looked upon as the origin of mountain chains. What began in the earlier and prehistoric times of geological history, seems to have been going on steadily down to the present day, and thus it happens, that geologists can prove mountain chains to be of very different ages, and that, of whatever age they may chance to be, the strata that compose them are found to be bent and contorted. This contortion of strata took place simply from that shrinking of the earth's crust which was the natural result of radiation of heat into outer space. Portions of the crust more or less gave way to lateral pressure, while other parts of the great spheroidal curve more or less retained what we call horizontal or nearly horizontal position.

In this way it happened that at a certain period of geological history which preceded the formation of the Miocene rocks in the region now occupied by the Alps, a disturbance of the earth's crust took place, due to shrinkage of the general mass, of such a nature that the Alpine strata were thrown into highly-contorted forms, and a great mountain range of pre-Miocene age was the result. On the north of these mountains the Miocene strata began to accumulate in great lakes. But these lakes lay so near the level of the sea, that every now and then, by depression of the land, they sometimes sank a little below the sea, and the sea invaded the area formerly occupied by fresh water. The result was that in Switzerland, between the Oberland and the Jura, and much farther north, the Miocene strata which are hundreds and sometimes thousands of feet thick, are now found to consist of interstratifications of marine, brackish, and of fresh-water beds. At that time the Jura had no existence. It is the result of a later disturbance of the crust of the earth, and thus it happened that all the Miocene waters in which were deposited the strata that now lie between the Oberland and the Jura originally spread northwards far across the area now occupied by the Jura, and into the district of the present plain of the Rhine between Basle and Bingen.

It is hard to realise the scenery of that time; but partly by an effort of imagination, and partly by special knowledge of the fossils contained in the rocks, it is possible to form some conception of the appearance of the country.

On the east and west of the great valley were mountainous ranges now called the Schwartzwald and the Vosges, while far to the south rose the high mountains of the pre-Miocene Alps, more or less covered with a forest vegetation. On the banks of the lakes there grew in an early stage of the Miocene epoch vast numbers of forest-trees and evergreen shrubs, of genera such as are now characteristic of tropical and sub tropical countries; figs and vines, many species of Protoaceæ analogous to those that still grow in the Australian continent, together with cypress, sequoia, cinnamon, fan palms, and palmettoes, ferns, hornbeams, and buckthorns, all of genera still familiar, but mostly if not altogether of extinct species. At a later date this vegetation partly

died out, and was replaced by plane-trees, poplars, elms, willows, and maples; while cinnamons, figs, vines, laurels, and Protoaceæ still continued to flourish. In the woods, on the meadows, and in the waters respectively, the *Mastodon angustidens*, the rhinoceros, Chæropotamus, Dichobune, deer, Dinotherium, hippopotamus, crocodiles, salamanders, fish, and numerous other creatures roamed at pleasure, while the air and the land were tenanted by dragon-flies, ants, beetles, and other insects, of which more than 800 species have been distinguished.

I now come to the chief part of this lecture, which is to account for the origin of the Rhine: for at that earlier time the Rhine had no existence in this valley, and indeed there is proof that instead of the main drainage of the area, flowing from south to north as it does now through this valley, the waters drained from north to south; and the pebbles of the Schwartzwald, instead of being carried north as they are now, were carried southward by minor rivers, and found their way into Switzerland, thus helping to form some of the conglomerate rocks of which the Miocene strata of Switzerland to a great extent consist.

Not only had the Rhine no existence then, but the romantic gorge of the river, with which so many are familiar, had no existence either. It has been customary sometimes to attribute the formation of that gorge to violent disturbance and fracture of the strata, by which the waters were allowed to escape from south to north. I have no belief in such violent disturbances having any place in the modern economy of the world, nor yet in such cataclysmal action having ever affected the ancient world, as far as it is in the power of geologists to trace back events from the present day to the oldest known geological periods.

After the Miocene epoch had lasted for a long period of time, there occurred another disturbance of the European region, and of much of the rest of the world besides, though it is only the Alpine region and the countries north of the Alps that we have now to deal with. This second disturbance of the Alps produced a great upheaval of the Miocene strata. All the Miocene lakes that occupied the old lowlands of Switzerland and extended far east into what is now the Austrian dominions and into Asia itself,—all that area, as far as the Alps are concerned, was gradually heaved up high above the level of the sea, and those beds of conglomerates, sandstones, and marls that form the lowlands of Switzerland, and all across what is now the Jura, were disturbed to such an extent that the strata now forming the Righi and Rosberg and other sub-Alpine hills were partly raised to a height of at least 5,800 ft. above the level of the sea, and probably much more. The lower parts of Central Switzerland, about the Lake of Geneva, the Lake of Constance, and Neufchatel, still stand at heights of from 1,200 ft. to 1,300 ft. above that level. Then the range of the Jura first rose up to form a mountain-chain, and this is the proof of these disturbances. First we know that the Miocene rocks originally lay all the way from the Alps to the Taunus in flat-lying strata. During that period a vast quantity of Miocene pebbles were carried into the lakes, which were by and by consolidated into an exceedingly coarse conglomerate. Anyone who has ascended the Righi will remember that nearly the whole of it is formed of this coarse conglomerate, proving the prodigious amount of waste that the Alps underwent during the Miocene period. When we consider the amount of this waste, even though the waters of the Miocene period lay but little above the level of the sea, still in my opinion it is probable that the Alps themselves were then quite as high, if not higher, than they are now. For the prodigious amount of waste proved by the conglomerate, indicates the removal of an enormous amount of material from the pre-Miocene Alps.

After the disturbance which raised the Jura and the Miocene strata of the lowlands of Switzerland, this is what took place. Along with the contorted secondary strata of the Jura, the Miocene beds that previously covered them were thrown into a number of anticlinal and synclinal curves, and the greater part of the Miocene material over that area having since been removed by denudation, only a few outlying fragments of these strata remain, left in those wonderful upland basin-shaped hollows of the Jura, which still attest the original continuity of the Middle Tertiary deposits all the way from the base of the pre-Miocene Alps to the northern base of the Taunus.

When the post-Miocene disturbance of the whole of this area took place the general effect was, that much of the Swiss Miocene area was contorted and raised high into the air, while between the Jura and the Taunus, the equivalent strata were simply heaved up and tilted so as to form a long inclined plain sloping northerly and lying between the Vosges and the Schwartzwald, and the surface of which may have been about 1,200 or 1,300 ft. above the present level of the sea where Basel now stands, and about 1,000 to 1,100 ft. high where the opening of the gorge now begins near Bingen.

Before this wide-spreading disturbance took place, the Rhine had no existence, for up to that time such small rivers as occasionally ran in the more ancient Miocene valley flowed partly south. But when the inclined plain was fairly completed, the result in the long run was that for the first time the great general drainage of the area began to run from south to north, and the Rhine was established flowing at a height which we may roughly speak of as having been 500 ft. higher than now, because at that time all the great valley between Basle and Bingen was filled to that height with Miocene strata. We know this to be a fact by an examination of the valley on the right hand and the left, from Bingen towards Basle, for every here and there, we find table-shaped hills formed of flat-lying Miocene strata, which border the present alluvial plain of the Rhine and abut upon the more ancient mountains on either side. The history revealed by this fact is plain to anyone accustomed to reason on geological phenomena. The strata forming scarped slopes on opposite sides of the valley were once united, and their early continuity has been destroyed, simply by long-continued watery waste and denudation. They are indeed only the relics of an older phase of the physical geography of the district, when the surface of the plain stood about 500 ft. higher than it does at present.

Now when the Rhine first began to flow, the river then passed through a high upland valley with gently sloping sides that lay between the Taunus and the Hundsruck, and which in no manner resembled the precipitous cliffs that now bound the Rhine in the gorge below Bingen. The bottom of part of this old upland valley still forms a narrow terraced plain, immediately above and beyond the edge of the cliffy gorge of the Rhine. It is not always continuous on both sides of the gorge, but enough of it remains to attest its original continuity at heights of from 400 to 500 ft. above the present level of the river. Now what I wish to persuade you of is this, that the Rhine flowing in this valley by degrees began to cut out its own gorge, and that it was not produced by fracture. Every running river is busy eroding its channel, especially where the ground is at all steep. That is one of the main functions of running waters. They are constantly deepening their channels and carrying the sediments so formed from higher to lower levels, till in the course of time they find their way into lakes or the sea.

When we first enter the gorge of the Rhine, going southward, one feature that strikes the geological observer is the constant recurrence of this old terrace backed by the hilly country beyond. On the left bank, overlooking Bingen, the flat-topped spur of the Rochus-berg, about the same height as the tops of the neighbouring Miocene tabular hills, first strikes the eye. When fairly within the gorge below Niederheimbach, beyond its upper edge the old river plain is seen gently sloping to the north, while the sides of the gorge itself is seamed by numerous gullies worn by occasional torrents since the great ravine—a kind of canon—has been cut down to its present level.

At Welmich, below Niederheimbach, looking down the river, the edge of the terraced plain is seen receding northward in long perspective, and at Salzig, still further down, the features so well shown near Niederheimbach are again reproduced. The same outline occurs again and again all down the river between Bingen and Coblenz, and equally below Andernach, as for instance at Rheineck. Finally, above the Siebengebirge, just about the mouth of the gorge, looking up the river, the long eastern hills sloping to the river end in a terrace corresponding in general height and outline to those already mentioned. The general conclusion to be drawn from these observations is that at heights of from 450 to 500 ft. above the present river this ancient river terrace has a persistent gentle slope from south to north which approximately corresponds to that of the existing river.

The inference is plain: that formerly throughout the length of what is now the gorge the river flowed at that high terraced level, at a time when the plain above the gorge was so deeply filled with Miocene strata that the level of the river, where Mainz and Bingen now stand, was as high as the upland terrace that crowns the gorge between Bingen and Rolandseck. By degrees the river began to excavate the gorge, and slowly cutting deeper and deeper, and at the same time winding and ever changing its channel through the great plain between the Jura and the Taunus, by slow gradation it wasted away the surface of that plain more and more, and the matter won from that

surface was carried down through the gorge to be added to the old delta of the river. At last the major part of the Miocene rocks that partly occupied the plain were worn away and the plain has been reduced to its present temporary level; while the terraced hills on either bank still remain to attest the amount of watery degradation that the area has undergone.

So much for the scooping out of the valley. But there is another point which I would like to impress upon you. On each side of the Rhine there are important tributary rivers. Thus, for example, above the gorge we have the Maine, the Neckar, the Kinzig, the Elz, and other streams, flowing through deep steep-sided valleys; and these rivers have from a very early period been tributaries of the Rhine. It follows, then, that when the level of the Rhine was 400 or 500 ft. higher than at present the levels of the bottoms of these rivers must also have been 400 or 500 ft. higher than at present; and therefore, just in proportion as the great valley of the plain of the Rhine was being cut down and lowered, so in proportion must the valleys in which these rivers run have gradually been deepened. When we come to the gorge the same kind of argument applies to the Moselle and other tributaries of the Rhine.

I have elsewhere attempted to show that at one time the Moselle ran as high as the top of the table-land that now bounds it on each side. Everyone who knows that river is aware that, though it looks so hilly when we go up the stream in a steamboat, as soon as we reach the edges of the slopes on either side we are on the top of a great table-land intersected by numerous valleys, so that before the gorge of the Rhine was formed the Moselle ran at as high a level as the ancient Rhine; and just as the gorge of the Rhine was being deepened, so the Moselle was by degrees also enabled to deepen its channel. The same was the case with other rivers, right and left of the Rhine; and by applying this principle to the other great rivers of Europe we may hope in the long run to explain the physical history of all the systems of drainage of all parts of the continent.

One other point remains to be stated with regard to the physical history of the Rhine. Geologists well know that in older times the glaciers of Switzerland were on an immensely larger scale than at present. Large as they appear to us at the present day, they are of pigmy size when compared with their magnitude at a comparatively late period of the world's history. The Rhone glacier then spread across all the area now occupied by the Lake of Geneva, till it abutted on the Jura; and the old Rhine glacier extended all over the Lake of Constance, and reached at least half way from Schaff haussen to Basle. The body of water which flowed directly from such glaciers must have been very great, and enormous must the moraines have been that were shed from the ice-sheets. From an examination of the pebbles that form the superficial gravel on the present plain of the Rhine below Basle, it is certain that a large portion of them have come from the Alpine regions. Such a great moraine as was shed from the western edge of the old glacier of the Rhine was constantly being attacked by the waters that flowed from its end, and thus by degrees pebbles were carried onward into the plain. The result is that a large part of the gravels of the Rhine is simply the waste of old moraines shed from the glaciers of Switzerland, added to by material carried down by the streams of the Vosges and the Schwartzwald, also partly derived from the moraines of ancient glaciers on a smaller scale.

Last year it was my lot to deliver here a lecture on the history of old continents, and I attempted to show that one old continent in particular retained its identity through a very long period of geological time; that from the close of the Upper Silurian period, all through the Old Red Sandstone and Carboniferous periods, through the Permian and New Red Sandstone epochs, over great part of what is now Europe, that continent, with many physical changes, still retained its identity. Such a vast continent remaining through all those geological periods implies a succession of epochs of time, which, as far as years and cycles of years are concerned, the mind has as yet only hints of data which some day may help us to grapple with such a problem, and not till astronomy comes more boldly to the help of geology, may we begin to hope for the solving of the problem of the actual value of geological time. However that may turn out, it is certain that during the long continental epoch alluded to there were, over and over again, many changes in physical geography far greater than that petty change which I have been endeavouring to sketch out to-night. The floras and faunas of the world in that old time changed, not in the minor degree I have been speaking of to-night, but were more completely remodelled again and again in great part, even generically. Mountain ranges rose, glacial periods intervened and passed away. Great lakes, sometimes fresh, sometimes salt, appeared and were obliterated by great terrestrial changes. At one time vast lakes, like those of the heart of Africa and North America, covered prodigious areas of land; at another, equal or larger areas were covered by salt lakes as large as the Caspian and the Sea of Aral. And when you think of the continental episode in the modern geological history of Europe to which I have drawn attention, you will see how small it really is, though it may look large to our minds, compared to the old continental epoch of which I spoke last year. This you may depend upon, that though to the superficial eye it may seem as if the world had always been going on just as it is doing now, and that through all time to come it will go on just the same, with its mountains, valleys, rivers, lakes, and seas, yet it is none the less certain that changes, such as I have described to-night, are but the forerunners of other mutations as great, aye, and far greater, that will take place in the future. Just as there is as yet no certainly measured limit to the geological time of the past, so also we know of no measurable limit to geological time to come. But why should I keep you with words such as these, when I may convey a whole chapter in physical geology, condensed into eight lines, by the greatest of our living poets :— .

There rolls the deep where grew the tree.
O Earth, what changes hast thou seen!
There, where the long street roars, hath been
The stillness of the central sea.

The hills are shadows, and they flow
From form to form, and nothing stands:
They melt like mist, the solid lands,
Like clouds they shape themselves and go.

SCIENTIFIC SERIALS

In the *Journal of Botany* for March, the editor, Dr. Trimen, commences a series of useful articles (which is continued in the April number) on the Botanical Bibliography of the British Counties, being a list of country and district floras arranged topographically. The other paper of greatest interest in this number is one of a kind of which this very useful journal has now published a considerable number, and which may ultimately throw considerable light on some of the problems connected with the distribution of plants, On the Flora of the Leeds and Bradford District, by J. A. Lees.—The number for April commences with an article of some importance in systematic botany, A Revision of the genera *Dryobalanops* and *Dipterocarpus*, by Prof. Thiselton-Dyer, in which a number of new species are described, including two belonging to the previously monotypic genus *Dryobalanops*, and illustrated by a plate (two more being promised in the next number). The editor also gives in this number one of the most valuable specialities of the journal, his list of New Species of Phanerogamous Plants in periodicals published in Great Britain during 1873.

The *Scottish Naturalist* for April publishes a number of papers on almost every branch of Botany and Zoology, including one on Geology, of more or less interest to Scottish naturalists.—Mr. J. A. Harvie Brown proposes the establishment of a Natural History Publication Society, something on the model of the original plan of the Ray Society, for the purpose of publishing original papers on Natural History, principally on Mammalia and Aves, and for reprinting in fac-simile rare and useful tracts, pamphlets, &c., on the like subjects.—We have also further instalments of the lists of the Lepidoptera and Coleoptera of Scotland, by Dr. Buchanan White and Dr. D. Sharpe. This quarterly magazine seems to fill a most useful place in forming a channel of intercommunication between naturalists north of the Tweed.

Memorie della Soc. degli Spectroscopisti Italiani, December. This number contains a paper be G. Lorengoni, On the Observation of a partial eclipse of the sun in May last, observed by the spectroscopic and direct view methods. He discusses at length the advantages and accuracy of each method, and concludes that the former method is the best of the two.—G. de Lisa gives a table of spots on the sun, observed at Palermo in December, giving a mean of about eight spots each day.

The January number contains a note that a new Spectroscopic Station has been established at Turin, and an equatorial by Fraunhofer has been erected there.—Prof. Draper contributes a

paper on his beautiful diffraction of spectrum photographs, similar to the account of the same in NATURE some weeks ago.

Astronomische Nachrichten, No. 1,978.—M. M. Henry gives the elements of planet (126) Velléda, epoch 1874, January, 0·0 Greenwich M.T.

$$\begin{aligned} Mo &= 149^\circ\ 55'\ 51''\cdot 1 \\ \Pi &= 347^\circ\ 49'\ 11''\cdot 3 \\ \Omega &= 23^\circ\ 10'\ 12''\cdot 8 \\ i &= 2^\circ\ 56'\ 10''\cdot 6 \\ \phi &= 6^\circ\ 5'\ 31''\cdot 4 \\ \mu &= 930''\cdot 9792 \\ \log.\ a &= 0\cdot 3873777 \end{aligned}$$

Leopold Schulshof gives the following elements of the comet discovered by Winnecke in February last :—

$$\begin{aligned} T &= 1874,\ \text{March},\ 9\cdot 95342\ \text{Greenwich Time} \\ \Pi &= 300^\circ\ 36'\ 42'' \\ \Omega &= 31^\circ\ 31'\ 18''\cdot 2 \\ i &= 58^\circ\ 17'\ 14''\cdot 5 \\ \log.\ q &= 8\cdot 642852 \end{aligned}$$

The star in Perseus RA $2^h\ 13^m\ 56^s$ Dec. + 58° 1′ 53″·5 has been observed by A. Krüger to have varied from 8·5 mag. to 10 mag. in November 1872, and to have increased to 8·5 again in January last.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, March 25.—John Evans, F.R.S., president, in the chair.—The following communications were read : —On the Upper Coal-Formation of Eastern Nova Scotia and Prince Edward Island, in its relation to the Permian, by Principal Dawson, F.R.S. The author described the Carboniferous district of Pictou county as showing the whole thickness of the Carboniferous system arranged in three synclinals, the easternmost consisting of the Lower series up to the Middle Coal-formation, and including all the known workable Coal-measures in the district—the second towards the west of the middle and the lower part of the Upper Coal-formation—and the third showing in its centre the newest beds of the latter. On the north the bounding anticlinal of the first depression brings up the New-Glasgow Conglomerate, which contains boulders 3 ft. in diameter, often belonging to Lower Carboniferous rocks, and represents the upper part of the Millstone-grit or the lower part of the Middle Coal-formation. The author regards this as representing an immense bar or beach, which protected the swamps in which the Pictou main coal was formed. The succession of the deposits above the Conglomerate was described in some detail as seen in natural sections. The Upper Coal-formation, as shown in the section west of Carribou Harbour, consists of—(1) Red and grey shales, and grey, red, and brown sandstones ; and (2) Shales, generally of a deep red colour, alternating with grey, red, and brown sandstones, the red beds becoming more prevalent in the upper part of the section. In Prince Edward Island beds apparently corresponding to these are found, and also gradually become more red in ascending. These are overlain, apparently conformably, by the Trias. The author gave a tabular list of 47 species of plants found in the Upper Coal-formation of Nova Scotia and Prince Edward Island, and stated that all but about ten of these occur also in the Middle Coal-formation. The number of species decreases rapidly towards the upper part of the formation ; and this is especially the case in Prince Edward Island, some of the beds in which are considered by the author to be newer than any of those in Nova Scotia. The plants contained in the upper deposits were compared with those of the European Permian, and a correlation was shown to exist between them, so that it becomes a question whether this series was not synchronous with the lower part of the Permian of Europe, although in this district there is no stratigraphical break to establish a boundary between Carboniferous and Permian. The author therefore proposes to name these beds Permo-Carboniferous, and regards them as to some extent bridging over the gap which in Eastern America separates the Carboniferous from the Trias.—Note on the Carboniferous Conglomerates of the Eastern Part of the Basin of the Eden, by J. G. Goodchild.—An Account of a Well-Section in the Chalk at the north end of Driffield, East Yorkshire, by R. Mortimer.—On Slickensides or Rock-Striations, particularly those of the Chalk, by Dr. Ogier Ward.

Royal Horticultural Society, April 1.—Scientific Committee.—Dr. Hooker, C.B., Pres. R.S., in the chair.—Prof. Thiselton Dyer exhibited seeds of the plant called in gardens *Theophrasta imperialis*, sent from Rio Janeiro by Dr. Glaziou. From the evidence now forthcoming it appears that the plant belongs to a different family, *Sapotaceæ*.—Dr. Hooker showed a photograph from Mr. Russell, of Falkirk, of a fruiting specimen of *Encephalartos villosus*, sometimes called in gardens *Zamia Mackenii*. The plant is a native of Natal, and a similar species has been discovered on the Niger by Barter, and a third in Zanzibar, by Kirk. A plant discovered by Schweinfurth in Central Africa is probably the same as that mentioned by Kirk.—Dr. Masters presented a classified list with notes of species of Passiflora and Tacsonia cultivated in European gardens.—Mr. Renny made some observations on the drawing, by Montagne, of *Artotrogus*, exhibited at the last meeting, which together with the original specimens, Mr. Berkeley had been kind enough to allow him to examine leisurely. He was able to clear up a mistake which De Bary seems to have fallen into in his description of *Peronospora infestans* (Ann. des Sc. Nat., 4e sér., t. xx. p. 105, 1863). De Bary had not met with the resting spore of that species, but suggested that Montagne's *Artotrogus hydnocarpus* might be the desired organ ; but he had doubts on the point, as Montagne had written to him that he found it also on Turnip. The facts are, that Mr. Broome found a mould on decaying Turnip, which he sent to Montagne, who pronounced it to be a species of his genus *Artotrogus*, though he does not appear at any time to have supplied a specific name. He doubtless announced to De Bary that *Artotrogus* was to be met with on Turnip, and it was De Bary's assumption that *A. hydnocarpus*, the only published species, was the one spoken of. De Bary, having a confident belief that the various species of *Peronospora* are parasitic each only on the plants of one genus, or at most of one family, seems to have been thus led to the doubt he has expressed.

General Meeting.—H. Little in the chair.—Prof. Thiselton Dyer commented on the interesting plants exhibited. Amongst these were the two forms of *Primula verticillata*, one from Sinai the other from Abyssinia ; *Boronia megastigma*, a new Australian plant with a very agreeable smell ; the stem and foliage of the splendid Bamboo *Dendrocalamus giganteus*, in cultivation at Sion House ; and cut blooms of *Sterculia nobilis* from the same collection.

Entomological Society, April 6.—Sir Sidney S. Saunders, president, in the chair.—Mr. Frederick Smith made some interesting observations relative to the habits of the bee-parasites belonging to the genus *Stylops*.—Major Parry communicated a paper entitled Further Descriptions of Lucanoid Coleoptera ; and Mr. Smith read descriptions of the *Tenthredinidæ* and *Ichneumonidæ* of Japan, from the collections of Mr. George Lewis.—Further notes were read from Mr. Gooch, of Natal, respecting the destruction of the coffee plantations there, by Longicorn Beetles.

Royal Astronomical Society, April 10.—Prof. Adams, president, in the chair.—Mr. De la Rue gave a verbal description of a piece of apparatus which he had devised for carrying out M. Janssen's method of photographing Venus near to ingress and egress upon the sun's disc. The instrument is intended to be attached to the photo-heliographs and weighs less than 11 lbs., inclusive of a small driving clock, which carries a revolving plate of about 10 in. in diameter, on which small photographs of Venus and the sun's limb are to be taken in rapid succession. Lord Lindsay also described the form of instrument which he had devised for the same purpose ; it appeared to be very similar to that described by Mr. De la Rue, except that it is mounted on a separate pillar from the telescope in order to avoid tremors.—Lord Lindsay also read a paper On a Method of Determining the Solar Parallax, from observations to be made at the next opposition of Juno, which occurs in November of this year. He proposes, while in the Mauritius, to make a series of heliometric measures of the distance of Juno from the nearest fixed stars ; and by comparisons of the measures taken soon after Juno has risen above the eastern horizon with those taken before it sets at the western to determine the terrestrial parallax. By this method he will be able to make his measures during all the clear nights of the month or six weeks before and after opposition. And although the parallax will be considerably less than in the case of Venus, he considered that he had reason to hope that the probable error of the result would, owing to the number of the

measurements and the ease of dealing with points of light instead of discs, be less than either in the case of the transit of Venus or the opposition of Mars.

Society of Biblical Archæology, April 7.—Dr. Birch, president, in the chair.—The following papers were read: On Four Songs contained in an Egyptian Papyrus in the British Museum. Translated with notes by C. W. Goodwin. Of these four songs three partook of the same nature, and were amatory compositions, written in a highly imaginative and poetical style with much voluptuousness of expression, having a very striking resemblance extending throughout whole passages, to the language of the Canticles. The fourth song or hymn is of a very different nature, and is evidently one of the solemn dirges used at festivals during the exhibition of the figures of Osiris, as related by Herodotus. This hymn is in the text ascribed to King Antuf, a monarch of the XIth dynasty.—Nimrod et les Ecritures Cuneiformes, by Joseph Grival (read in English). In this essay the author maintained that Merodach, under his Accadian name of "Amarud the eldest son of the Lord of Urhi," was identical with Nimrod the "géant chasseur" of the Septuagint.

EDINBURGH

Royal Physical Society, March 25.—On some Organisms found in the Stomach of the Herring, by F. W. Lyon.—Note on Entozoa, genus *Bothriocephalus*, found in the intestinal canal of a fish (*Cottus scorpius*), by James M'Bain.—On Recent Meteoric Chemistry, by Andrew Taylor. Mr. Taylor, in this paper, gave a *résumé* of the present state of our knowledge of the chemistry of meteorites.—On British Madreporiæ, by C. W. Peach, A.L.S. Mr. Peach read a paper on this subject, first stating that his attention had been drawn to the subject by a paper by Prof. P. Martin Duncan, on the Madreporiæ dredged by the explorers in the *Porcupine* in 1869 and 1870. He then exhibited a series of specimens he had collected in the seas of Shetland, Cornwall, &c., the most abundant being Caryophyllia, varieties *Smithii* and *Borealis*.—On the Fossil Plants of the Silurian Rocks of the Pentland Hills and of Sutherlandshire, by C. Wm. Peach, A.L.S. In this paper Mr. Peach showed that one of the large plants collected by Mr. Brown in the Upper Silurian rocks of the Pentlands was identically the same and in a similar matrix as the one collected by him in Sutherlandshire. This same plant had also been found in the Upper Silurian of the Iuaspe sandstones in Canada. He further said that the rocks in Sutherlandshire were Lower Silurian, thus showing that land plants—and of a pretty high type—came in much earlier there than from either of the other localities.

PARIS

Academy of Sciences, April 6—M. Bertrand in the chair.—The perpetual secretary announced to the Academy the loss which it had sustained in the person of M. P. A. Hansen, correspondent for the Astronomical section, who died at Gotha on March 28.—The following communications were read:—On Polygons inscribed in and circumscribing curves, by M. Chasles. —Solar Cyclones: conclusion of the reply to Dr. Reye, and observations concerning an article from the "Bibliothéque universelle" of Geneva, and a reclamation by M. Norman Lockyer, by M. Faye. The author has tabulated the dates, localities, times, velocities, &c. of thirty-one cyclones.—Earthquake shocks felt in Algeria on March 28, 1874; a letter from M. Ch. Sainte-Claire Deville to the perpetual secretary. The communication included a note from Captain Brocard, containing a seismo-graphic indication of the shocks.—Observations made at the Observatory of Toulouse during the months of February and March 1874, by M. F. Tisserand. The author communicated observations on the eclipses of Jupiter's satellites, and announced at the same time that regular observations of sun-spots had been organised with an equatorial of 0·108 m. aperture, after the method of Carrington.—Experimental researches on bi-hydrated sulphuric acid, by MM. Js. Pierre, and E. Puchot. —Scientific ascent to a great height made (in a balloon) on March 22, 1874, by MM. J. Crocé-Spinelli and Sivel. The authors had ascended 7,300 metres, the temperature at that elevation being $-22°$. The observations recorded in this communication are spectroscopic and physiological. Particular attention was given to the two obscure bands right and left of the double D line. At about 5,500 metres the right-hand band dispppeared, and the band to the left vanished at about 7,000 metres, thus confirming M. Janssen's idea of these bands being of terrestrial origin. The observers adopted M. Bert's suggestion of respiring oxygen to correct the effects of the rarefaction of the air. A carrier pigeon released at 5,000 metres tried at first to remount to its cage, but finally descended, describing curves of from 200 to 300 metres in diameter, with a velocity of translation of about 40 or 50 metres per second.—Action of electric fluid upon gases, third note, by M. Neyreneuf. The author promised from his observations a satisfactory explanation of the stratification of the electric light. —On a new process for the study and determination of the alcohol in wines, by M. Duclaux. The process depends upon the fact that mixtures of alcohol and water give for different compositions different numbers of drops when allowed to flow from a pipette of constant orifice. (The method is a practical application of Dr. Guthrie's researches upon drops to which no allusion was made.)—Note accompanying the presentation of new astronomical objectives of large dimensions, by M. Secretan. The largest was 24 centim. in diameter and had a focal distance of 3·25 metres. Its price was 6,300f.—On a new (electric) couple specially prepared for the application of continuous currents in therapeutics, by M. J. Morin.—On a system of continuous alarm signals to prevent railway collisions or collisions of ships at sea during foggy weather, by M. C. J. de Mat.—Geological considerations on the probable origin of the drift soil called *diluvium*, by M. E. Robert.—On the employment of coal-tar alkalies for the destruction of *Phylloxera*, by M. A. Rommier.—Direct construction of the centre of curvature in a point of the section made in a surface by any plane, by M. A. Mannheim.—On the diffusion between moist and dry air through a septum of porous clay, by M. L. Dufour.—Measurement of the electromotive force of batteries in absolute units, by M. A. Crova.—Density of hydrogen combined with metals, by MM. L. Troost and P. Hautefeuille. The observed density is about 0·625.—Experiments concerning combustion in the animal organisation, by M. P. Schutzenberger.—On the brominated derivatives of pyruvic acid, by M. E. Grimaux. The author described di- and tri-brompyruvic acids and touched upon the constitution of the acid itself.—Modifications employed in the preparation of iron reduced by hydrogen, for the purpose of obtaining the metal perfectly pure, by M. Crolas.—Note on the determination of lime in meteoric waters, by M. H. Marié-Davy.—On asphyxia from insufficiency of oxygen, by M. Félix le Blanc.—On the use of oxygen in ballooning, by M. W. de Fonvielle.—Injection of ammonia into the veins to oppose accidents caused by snake bites, by M. Oré.—On the functional irritability of the stamens of *Berberis*, by M. E. Heckel.

THURSDAY, APRIL 23, 1874

HERBERT SPENCER'S SOCIOLOGY

The Study of Sociology. By Herbert Spencer. (London: Henry S. King and Co.)

THERE are not a few signs, of which the book before us is an important one, that thought is moving in the direction indicated by Mr. Mill in the quasi-prophetical conclusion to his "System of Logic," where he expresses his belief in the prominence of sociological inquiries in the intellectual achievements of the next two or three generations of European thinkers. What has been called by Hegel the speculative historical method has taken a considerable step in advance since Mr. Mill wrote thus. History, written from the speculative or philosophical stand-point, may be regarded as a special Sociology—Sociology, that is, applied to the investigation of the laws of growth and development of some one society, as exhibited either throughout its whole career, or within some limited period. General Sociology stands to history in a position analogous to that occupied by general physiology with regard to the special physiology of man or of any other species of animal. This analogy will serve to throw some light upon the fact that there has been much greater progress made in the special department of speculative history than in the wider field of Sociology. Up to a certain point, the broader generalisations of the higher science must be preceded by the more restricted generalisations of the lower. But when this point has been reached, when the higher principles have been formulated with approximate completeness, then the advances along the lines of general and special thought will proceed *pari passu;* progess in one will by its reflex influence make possible a correlative progress in the other. The relations between Sociology and history appear to be nearing this stage.

Division of labour obtains in literature as well as in industry. His special turn of mind, not less, perhaps, than the character of the task to which he has devoted himself, has made Mr. Spencer a labourer in the wider field of Sociology. The volume under review, taken in connection with the two parts already issued of the "Descriptive Sociology," of which Part I. has been noticed here,* enables us, to some extent, to anticipate the character of the more elaborate and comprehensive work, the "Principles of Sociology," the promised fourth division of Mr. Spencer's "System of Philosophy." In the "Descriptive Sociology" we have an insight into the laborious thoroughness with which Mr. Spencer is preparing the foundations for his generalisations, while in the "Study of Sociology" we are introduced to his conception of the nature of the social science, of the difficulties in the way of the sociologist, and of the discipline necessary to the formation of a habit of thought adapted to sociological inquiries.

It is not necessary here to follow Mr. Spencer into the polemic contained in the first two chapters of his book, directed against the popular notions of sociological phenomena; against the dogmatic, unscientific, and off-hand way in which important and complicated sociological questions are decided not only by the vulgar, but also by men who are guided by a strict scientific method in the less intricate questions of physical science; and against the supporters of the special-providence and great-man theories of history. Mr. Spencer being the assailant, it is almost superfluous to say that the polemic is a vigorous one; indeed it may be open to question whether the assault would not have been more successful had it been conducted with less vigour and more circumspection. To use Mr. Spencer's own metaphor, a considerable correction for the "personal equation" of combativeness will be found necessary.

The possibility of a science of Sociology is shown in various ways. One cause of the denial of this possibility is to be found in the prevalent confusion between a science and an exact science. Sciences are either merely logical or mathematical also; in Mr. Spencer's phraseology, qualitative or quantitative. It is not affirmed that Sociology can be a quantitative science; but this is not to deny its scientific character altogether. Sociology presents in an extreme form that absence of quantitative definiteness which geology, biology, and psychology present in a considerable, though less, degree. Mr. Spencer puts his own case and that of the objectors to the scientific character of Sociology very forcibly in the following dilemma:—"In brief, then, the alternative positions are these. On the one hand, if there is no natural causation throughout the actions of incorporated humanity, government and legislation are absurd. Acts of Parliament may, as well as not, be made to depend on the drawing of lots or the tossing of a coin; or rather, there may as well be none at all: social sequences having no ascertainable order, no effect can be counted upon—everything is chaotic. On the other hand, if there is natural causation, then the combination of forces by which every combination of effects is produced, produces that combination of effects in conformity with the laws of the forces. And if so, it behoves us to use all diligence in ascertaining what the forces are, what are their laws, and what are the ways in which they co-operate."

Sociology is concerned with men aggregated into societies. Aggregates derive their essential properties from the natures of the individuals of which they are composed. Aggregation, though it may foster the development of some, and check that of others, of the characters of the constituent units, cannot give rise to social properties for which there is no foundation in those of the components. Setting out from this axiomatic principle, Sociology describes "the growth, development, structure, and functions of the social aggregate, as brought about by the mutual actions of individuals whose natures are partly like those of all men, partly like those of kindred races, partly distinctive. . . . Not that the social science exhibits these or those special truths, but that, given men having certain properties, an aggregate of such men must have certain derivative properties which form the subject-matter of a science."

Nowhere, perhaps, than in sociological phenomena is the truth of the doctrine of evolution, the central doctrine of Mr. Spencer's philosophy, more strikingly displayed, and nowhere, subject to proper limitations, is it likely to prove more serviceable. To borrow Comte's phraseology, Sociology is either dynamical or statical. The dynamics of Sociology is throughout an exemplification of evolution.

* See NATURE, vol. viii. p. 544.

The statics of Sociology, at any given epoch, deals with phenomena which are the results of evolution. When Sociology is regarded in its dynamical aspect, the doctrine of evolution properly understood and limited, recognising and accounting for both the relative perfection and imperfection of a given social state, occupies the true mean between the altogether optimist view of social progress which finds expression in the lines—

As round and round we run,
Ever the truth comes uppermost,
And ever the right is done;

and the altogether pessimist view embodied in the dictum of a distinguished living thinker, "The history of mankind is a huge *pis-aller*." But when Sociology is regarded in its statical aspect, an abusive use may easily be made of the doctrine of evolution. A given social state bears a relation to the past social states from which it is an outgrowth, and also to existing circumstances and conditions. Led away by the tendency of modern thought, so happily described by Mr. Bagehot as making everything "an antiquity," the sociologist is apt to dwell upon the first of these relations, to the exclusion of the second. From such one-sidedness Mr. Spencer does not appear to be altogether free.

It is always useful to know the nature, the magnitude, and the position of the difficulties that have to be encountered in the course of an inquiry. Mr. Spencer has given more explicitly and in fuller detail than any previous writer has done, an analysis of the difficulties in the way of sociological investigations. These difficulties are objective and subjective; difficulties inherent in the object of sociological science, and difficulties originating in the observer himself. The data of Sociology, the actions of men incorporated into societies, are distributed over long periods of time, and wide areas of space. The sociological inquirer must necessarily rely for his data upon past and contemporary records. But records may not exist; deep-lying circumstances of importance may be obscured by superficial circumstances; evidence will suffer vitiation through the want of perspicacity or of impartiality in the observer. A comprehensive, patient, and judicious employment of the comparative method is the only means by which order can be educed out of the chaotic mass of data which the recorded histories of societies offer. Mr. Spencer and his collaborateurs will deserve the gratitude of every sociological inquirer, for the extensive collection and collation of these materials, now in progress in the atlas-like folios of the "Descriptive Sociology."

Formidable as are the objective difficulties which beset sociological researches, not less formidable are the subjective difficulties. This class of difficulties originates either in the intellectual or in the emotional character of the observer. The want of a faculty adequate in plasticity and complexity to the many-sidedness and complexity of the object of investigation, and the tendency to automorphism, to make self the measure of things, are the principal intellectual obstacles to Sociology. Automorphism is one of the most fertile sources of error. "To understand," says Mr. Spencer, "any fact in social evolution we have to see it as resulting from the joint actions of individuals having certain natures; and this even by care and effort we are able to do but very imperfectly. Our interpretation must be automorphic; and yet automorphism perpetually misleads us."

In Sociology man is at once the observer and the observed; the inquirer is a unit of the aggregate whose laws he is investigating. We may observe a transit of Venus with the impartiality due to the absence of personal concern; we are not impartial observers of a social event with which our own interests are intimately bound up. Accuracy of observation is thus interfered with by sentiment. From the observer's emotional nature spring the various kinds of bias, educational, patriotic, class, political, and theological, described and abundantly exemplified by Mr. Spencer in a succession of chapters deserving of careful study, but to which space prevents more than a reference.

Attention to questions of scientific discipline and method is so rare among scientific men, that Mr. Spencer's book would deserve commendation for this feature, if for no other. Discipline should have reference to the work to be performed. Sociology being the most complex of the sciences, the sociological inquirer needs a discipline capable of producing an adequately powerful instrument of research. Falling back upon his classification of the sciences, into Abstract sciences, which investigate the *forms* of phenomena, Abstract-concrete sciences, which investigate the *factors* of phenomena, and Concrete sciences, which investigate the *products* themselves in their totality, Mr. Spencer shows the need in Sociology of the discipline in the necessities of relation derived from the first; in the distinctness given to the notion of simple causation derived from the second; and in the formation of the conception of continuous, complex, contingent, and fructifying causation derived from the third. Not, of course, that there can be an exhaustive or even a deep study of all or any of these sciences; a disciplinary study is all that is contended for, a study sufficient to enable the sociological inquirer to grasp the cardinal ideas proper to each science. But there is a more intimate dependence of Sociology upon the sciences of physical and psychical life, therefore the sociologist stands in need of a deeper acquaintance with biological and psychological truths. Amongst the most interesting and valuable chapters in the book are those in which Mr. Spencer enforces the need of an adequate preparation in biology and psychology. Positive arguments are supplemented by negative arguments, arguments based upon striking exemplifications of the errors that have arisen in the practical sciences of politics and education from ignoring biological and psychological teachings.

The view taken by Mr. Spencer of the method proper to sociological inquiries seems, as far as can be gathered from his own procedure, to differ little from that advocated and expounded by Mr. Mill. Placing Sociology next after psychology in his System of Philosophy, and asserting, as he does everywhere, the dependence of social phenomena upon psychological facts connected with the social units, Mr. Spencer's method appears to be to trace out deductively the connection of the empirical sociological truths, arrived at by generalisation from the data furnished by historical records, with the ultimate laws of human nature established by psychology. This is essentially Mr. Mill's inverse or historical deductive method applied to sociological inquiry.

In its style the "Study of Sociology" somewhat disagreeably reminds the reader of one of Mr. Spencer's earliest works, "Social Statics." It has two main faults—it is needlessly polemical in its tone, and it is disfigured by numerous unscientific exaggerations of language. Mr. Spencer is undoubtedly right in defending against Mr. Arnold the superiority of the guidance of psychology and logic, over mere linguistic culture, in producing a style clear, forcible, and free from tautology. But there is neither psychological nor logical defence for the two faults indicated. Amongst minor faults of style may be enumerated an occasional laxity in the use of analogies; the degeneration of the psychologically sound practice of prefacing the enunciation of an important truth by a forcible illustration of it into a disagreeable mannerism, some very marked examples of which occur in the opening paragraphs of several of the chapters; the frequent occurrence of words ineuphoniously formed, to say the least of them, such as "re-revenge," "irrelation," "wholesaler;" and the overabundant formation of compounds, especially noticeable in the compounding of the adjective and its qualifying adverb, as in "logically-conclusive," "profoundly-untrue," "equally-long."

Some of the defects pointed out are probably traceable to a desire to popularise the work as far as possible, in forgetfulness, to some extent, of the necessity to maintain the character which should appertain to it as one of a scientific series. But, while it is to be regretted that there should be such blemishes to mar the general effect of a book so full of suggestive thought and of appropriate illustrative facts, it must be allowed that the "Study of Sociology" forms a valuable addition to sociological literature, and leads the student in this department of human thought to anticipate with pleasure the appearance of the work to which it and the "Descriptive Sociology" are but forerunners.

W. H. BREWER

FRITSCH'S "SOUTH AFRICAN RACES"

Die Eingeborenen Süd-Afrika's, ethnographisch und anatomisch beschrieben. Von Gustav Fritsch. (Breslau: Hirt, 1872.)

IT is to be hoped that this work will have a good effect on the Science of Man, as a much-needed example which, once seen, will no doubt be followed. So far as the writer of the present notice is aware, the attempt at a systematic monograph of a race has never yet been made with so near an approach to success. With all our hundreds of volumes full of information as to the lower races of mankind, it is generally a difficult task for the ethnologist to piece together out of them anything like a complete picture of any tribe, with scientific fulness and accuracy of bodily, mental, social, geographical, and historical detail. Where, for instance, could he go for full information as to the two African races of whom Dr. Fritsch's work treats, the Kafirs and Hottentots?

The student's best source has been hitherto the conscientious dictionary-like summary, brief yet tedious, contained in 60 pages (Vol. II.) of Waitz's "Anthropologie der Naturvölker." The chapters in Mr. J. G. Wood's "Natural History of Man" are fuller and more life-like, but they are far too popular in topics as well as in style. Nor had either of these writers ever lived among the races about whom he compiled information. From a study of the descriptions drawn up by travellers, missionaries, and officials, who have known the Kafirs and Hottentots by

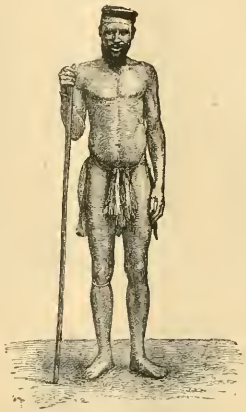

FIG. 1.—Zulu of Natal.

personal knowledge, it is possible to get much of the information wanted, but how long will it take even to glance over the volumes of Shooter, Galton, Callaway, Hahn, Casalis, Grout, Maclean, Andersson, and a dozen more? Each other savage or barbaric race of the world demands in like manner the reading through of a small

FIG. 2.—Young Kafir.

library, consisting mostly of miscellaneous literary matter, in which the ethnographic information is imbedded. The state of things is briefly this, that anthropological evidence is at present so bulky and so scattered, as to be

unmanageable except by those who can give half a lifetime to it. It is highly desirable to have the whole available knowledge as to each race condensed into a monograph like the present, by a competent ethnographer who knows that race by personal study in its home. It would be a real service to the ethnographers now at work drawing up accounts of native tribes in India and elsewhere, to put into their hands Dr. Fritsch's book as a model. As with all its excellencies of plan and execution, it is in many respects open to improvement, it would serve as a stepping-stone to yet more perfect works.

In popular language, the two indigenous races of South Africa are known as *Kafirs* and *Hottentots*, one the well-known Moslem term for "infidels" picked up by the Portuguese from the Arab traders of the sixteenth century, the other an imitative epithet, "hot-en-tot," given by the Dutch colonists to the tribes using "clicks" in their speech. Neither term is now satisfactory, and Dr. Fritsch is justified in adopting the native names by which the two races denote themselves. For the *Kafir* tribes he uses the term *Abantu*, *Bantu* (plural of *ntu*, a man), and for the *Hottentot* tribes their designation of *Koi-koin* (*i.e.* "men of men," from *koi*, a man).

Fig. 3.—Sandili's Wives.

Dr. Fritsch, as a professed anatomist, examines with almost exhaustive minuteness the bodily characters of these two races. The closer appreciation of race-types, which is now supplanting the vaguer generalities of twenty years ago, is in no small measure due to the introduction of photographic portraits, instead of the old misleading sketches by artists unable to clear their minds of the artistic types of Europe. Without photography it would be impossible to obtain a collection of portraits such, for instance, as those lately published in Colonel Dalton's "Descriptive Ethnology of Bengal." The portrait engravings from South African photographs in Dr. Fritsch's album (unfortunately arranged on somewhat different dimensions from the volume it accompanies) are at the same high level of truth and art. When race-types are so well-marked as among these South African tribes, even small figures will show their principal physical peculiarities. A selection from the small-scale woodcuts in the main volume, likewise taken from photographs, are here produced from copies of the blocks lent by the publishers.

Figs. 1 and 2, representing a middle-aged and a young Kafir, show the characteristic slimness of the figure, due to the wall-sided chest and narrow hips. The lean forearm, a peculiar conformation of the deltoid and biceps, a somewhat finely-formed hand, and an ungraceful setting back of the lower extremities and inclination of the pelvis, are other points of speciality. The narrow skull is well seen in the figures, with the broad-winged flattened nose showing the nostrils in full face, the fleshy pouting lips, and the hair naturally felted. Add to this the deep-brown colour of the skin, which is shown in No. 1 of the specimen tints given in a table at the end of the volume, with the deep-brown eyes and black frizzy hair, and the total as nearly represents the ideal Kafir of the Ama-Xosa type as ethnologists can conceive it. Fig. 3, representing a group of wives of a chief,* shows with coarse distinctness the typical Bantu features.

In strong contrast with this Kafir type is that of the Koi-koin or Hottentots, including as one of its divisions the Bushmen. Whereas the dark-brown or almost black Zulu stands little short of 5 ft. 8 in., the Hottentot, whose brownish-yellow complexion has been compared to a dry leaf, averages only 5 ft. 3 in., and the tiny dirty-yellow Bushman under 4 ft. 8 in. Bearing in mind their yellow complexion and diminutive size, some idea of the Bushman type may be gained from Fig. 4. The high cheek-bones and pointed chin give the face its peculiar triangular shape, while the characteristic snub-nose is shown in the old Bushman, Fig. 5.

Dr. Fritsch justly observes that the Bantu and Koi-koin races have hardly any essential race-character in common, unless it be the crisped hair; and even this is generally (though not through all varieties) distinct, the Bantu hair being irregularly felted into a mass, whereas the Koi-koin hair grows in little tufts, which have been compared to the bristles of a blacking-brush. The steatopygy of the Hottentot-Bushman women is shown by an extraordinary collection of portraits in Dr. Fritsch's volume; few physical race-characters are more striking than this, and it is unfortunate that illustrations of it cannot be inserted here. As in other parts of their structure, so in cranial proportions the two races in question are markedly distinct, as is fully proved by the set of lithographed skulls with tabulated measurements. The Kafir skull is narrow and high, the proportion of length to breadth being about 100 : 71·9, while the height may be taken at 73·8, being thus slightly greater than the breadth. The Hottentot skull, on the other hand, is narrow and low, the proportion of length to breadth being about 100 : 72·7, while the height of such a skull might be only 71, which is less than the breadth. The Bushman skull shows this character in still more extreme proportions in a cranium whose length is 100, the breadth

* This group illustrates in a curious way the conventional but not irrational development of the ideal of beauty from the ordinary forms of normal life. This ideal once fixed among any nation, there ensues a desire to exaggerate it. In the present instance, in grown-up Kafir women, the tendency of the breasts to become long and pendulous is considered not contrary to beauty, and is accordingly artificially increased by binding down, as shown in the figure.

being 73·8, against a height of 70·2, which gives about double the difference of the Hottentot.

The elaborate anatomical data amassed by Dr. Fritsch may afford the means of more fully working out the ethnological problems of the South African races. The evidence here brought forward of the more extreme characters of the Bushman type as compared with the Hottentot, seems to tell in favour of the view put forward by Prof. Huxley some years ago, that the Hottentots are the result of crossing between the Bushman and the Negroid tribes. Beyond this, there naturally arises another question: do the Kafir tribes, with their complexions varying from dark-brown to blue-black, owe their bodily differences from the Negro of Equatorial Africa to an intermixture of Bushman blood during a long course of ages. The evidence of language is here important. So far as it is concerned, the Kafir of South Africa is essentially a Negro, for his dialects belong to the great series of prefixing languages, the peculiar character of which is so well shown in the formation of the plural. Just as the Mpongwe language of the Gaboon makes the plural of *omamba*, snake; *imamba*, snakes; and farther east the individual inhabitant of *Unyamwezi* is a *Mnyamwezi*, and the people as a whole are *Wanyamwezi*:—so in Zululand *umuntu* is a man; *abantu*, men; and *Amazulu* is the plural name of the nation of whom an individual is *Uzulu*. The Bushman-Hottentot, or Koi-koin group of languages, are on the other hand distinguished by their tendency to monosyllabic words, their suffixes, and the "clicks" which to so extraordinary an extent are used as consonants. According to Dr. Bleek's classification, this family of languages has also relations farther north on both sides of the Continent; but this is a point which requires further examination. Now, though the fundamental types of the Kafir and Bushman languages are so absolutely distinct, it has come to pass that certain of the Kafir tribes, notably the Zulus, use to some extent in their speech clicks of the Hottentot type, whereas nothing of the kind

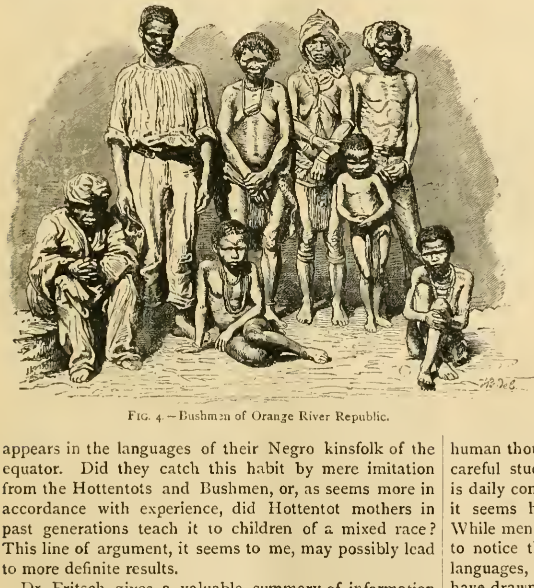

FIG. 4.—Bushmen of Orange River Republic.

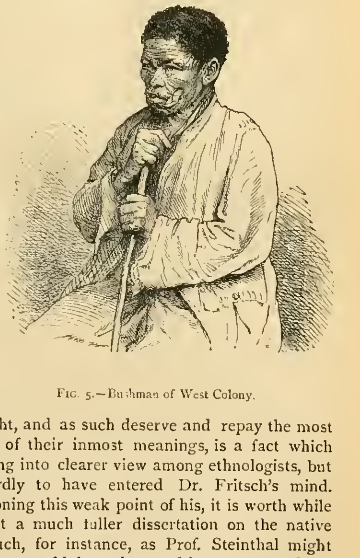

FIG. 5.—Bushman of West Colony.

appears in the languages of their Negro kinsfolk of the equator. Did they catch this habit by mere imitation from the Hottentots and Bushmen, or, as seems more in accordance with experience, did Hottentot mothers in past generations teach it to children of a mixed race? This line of argument, it seems to me, may possibly lead to more definite results.

Dr. Fritsch gives a valuable summary of information as to the industrial, social, and intellectual condition of the South African races. The latter is not, however, of such special excellence as the descriptions of physical race-characters. Indeed, Dr. Fritsch is on the whole a better judge of bodies than of minds. His account of the native religions is below his general level, as may be judged from his describing the Zulu religion without mention or apparently knowledge of the remarkable native documents collected by Dr. (now Bishop) Callaway, which throw such clear light not only on the religious ideas of these barbarians, but on the origin and development of religion among mankind at large. That savage theologies show representative stages in the evolution of human thought, and as such deserve and repay the most careful study of their inmost meanings, is a fact which is daily coming into clearer view among ethnologists, but it seems hardly to have entered Dr. Fritsch's mind. While mentioning this weak point of his, it is worth while to notice that a much fuller dissertation on the native languages, such, for instance, as Prof. Steinthal might have drawn up, would have been of interest to students whose wants are only partially supplied by the meagre though valuable classificatory sketch here given, mostly on the authority of Dr. Bleek. Our author also shows glimpses of ill-temper in dealing with authors he dislikes, such as Mr. J. G. Wood, whom he falls upon in season and out of season. An instance of the latter kind of attack is seen where Mr. Wood, speaking in perhaps too enthusiastic terms of the physical beauty of youthful savages, naturally introduced the well-known story of Benjamin West, the Quaker painter, comparing the Apollo Belvedere to a young Mohawk warrior. Dr. Fritsch, quite missing the point of the story, solemnly quotes Mr. Wood as asserting, in proof of the classical beauty of the

Kafirs, that "an American Quaker, West, took the statue of the Belvedere Apollo for the representation of a Mohawk Indian." Having made Mr. Wood talk this extraordinary nonsense, he then reviles him for being illogical. This is not the treatment Mr. Wood merits. No one denies the faults of his work, especially the unhappy straining after the picturesque which has made so many of his artist's illustrations worse than worthless. But his genial and suggestive descriptions of South African native life give a permanent value to his popular volume, while in his special line as a student of savage arts and implements, Dr. Fritsch can hardly expect to rival him.

EDWARD B. TYLOR

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Flowers of the Primrose destroyed by Birds

FOR above twenty years I have observed every spring in my shrubberies and in the neighbouring woods, that a large number of the flowers of the primrose are cut off, and lie strewn on the ground close round the plants. So it is sometimes with the flowers of the cowslip and polyanthus, when they are borne on short stalks. This year the devastation has been greater than ever; and in a little wood not far from my house many hundred flowers have been destroyed, and some clumps have been completely denuded. For reasons presently to be given, I have no doubt that this is done by birds; and as I once saw some greenfinches flying away from some primroses, I suspect that this is the enemy. The object of the birds in thus cutting off the flowers long perplexed me. As we have little water hereabouts, I at one time thought that it was done in order to squeeze the juice out of the stalks; but I have since observed that they are as frequently cut during very rainy, as during dry weather. One of my sons then suggested that the object was to get the nectar of the flowers; and I have no doubt that this is the right explanation. On a hasty glance it appears as if the foot-stalk had been cut through; but on close inspection, it will invariably be found that the extreme base of the calyx and the young ovary are left attached to the foot-stalk. And if the cut-off ends of the flowers be examined, it will be seen that they do not fit the narrow cut-off ends of the calyx, which remains attached to the stalk. A piece of the calyx between one and two-tenths of an inch in length, has generally been cut clean away; and these little bits of the calyx can often be found on the ground; but sometimes they remain hanging by a few fibres to the upper part of the calyx of the detached flowers. Now no animal that I can think of, except a bird, could make two almost parallel clean cuts, transversely across the calyx of a flower. The part which is cut off contains within the narrow tube of the corolla the nectar; and the pressure of the bird's beak would force this out at both the cut-off ends. I have never heard of any bird in Europe feeding on nectar; though there are many that do so in the tropical parts of the New and Old Worlds, and which are believed to aid in the cross-fertilisation of the species. In such cases both the bird and the plant would profit. But with the primrose it is an unmitigated evil, and might well lead to its extermination; for in the wood above alluded to many hundred flowers have been destroyed this season, and cannot produce a single seed. My object in this communication to NATURE is to ask your correspondents in England and abroad to observe whether the primroses there suffer, and to state the result, whether negative or affirmative, adding whether primroses are abundant in each district. I cannot remember having formerly seen anything of the kind in the midland counties of England. If the habit of cutting off the flowers should prove, as seems probable, to be general, we must look at it as inherited or instinctive; for it is unlikely that each bird should have discovered during its individual life-time the exact spot where the nectar lies concealed within the tube of the corolla, and should have learnt to bite off the flowers so skilfully that a minute portion of the calyx is always left attached to the foot-stalk. If, on the other hand, the evil is confined to this part of Kent, it will be a curious case of a new habit or instinct arising in this primrose-decked land.

Down, Beckenham, Kent, April 18 CH. DARWIN

Signor D'Albertis' and Dr Meyer's Discoveries in New Guinea

HAVING just returned to Europe, I read in NATURE, vol ix. p. 77, a communication which contains an assertion of Dr. A. B. Meyer, to the effect that I did not cross New Guinea at all, and that he claims the honour of having done so himself.

From what Dr. Meyer says, the public are led to believe that I have claimed the honour of crossing this unknown and little-explored island; if he had read "A Month among the Papuans of Mount Arfák," he might easily have ascertained that I never asserted this. There the reader will see that I only claimed to have penetrated the country to a distance of thirty miles, and to have ascended to a height of between 3,000 and 4,000 feet; but I *was* the first European to see alive and shoot many rare Birds of Paradise peculiar to New Guinea. One of these was entirely new to science, and has been called *Drepanornis albertisi* by Dr. Sclater (NATURE, vol. viii. p. 305); it may be the same bird subsequently described as new by Dr. Meyer.

I have no wish to deprive the last-named gentleman of the honour of having crossed a greater or lesser portion of New Guinea, but I object most decidedly, either indirectly or by insinuation, to being deprived of the credit of being the first European to penetrate into the interior of that interesting country.

April 20 LUIGI MARIA D'ALBERTIS

Spontaneous Generation

MR. RAY LANKESTER's letter in last week's NATURE affords fresh evidence of his lack of acquaintance with the several stages through which the "spontaneous generation" controversy has passed, or he would not now cite as a "most important result" only made known by recent experimentation, a fact which has been well known and repeatedly verified since the time of Spallanzani. I allude to the influence of the prolongation of the period of exposure to heat in retarding or altogether arresting the putrefactive tendencies of organic solutions. I have not thought it needful on previous occasions to point out the various misconceptions and the apparent ignorance of facts shown by Mr. Lankester in his querulous communications to your columns on the subject of "Spontaneous Generation." There are one or two points, however, to which I will now venture to solicit his attention, and that of your readers generally.

Mr. Lankester says:—"It is probably now familiar to those interested in the matter, that the experiments of Dr. Sanderson have established the fact that in an infusion of turnips and cheese prepared as directed by Dr. Bastian, heating to a temperature of 102° C. is sufficient to prevent the subsequent development of life (Bacteria) in the infusion, even when the exposure to that temperature is only maintained for a few minutes." To this statement I have to add that since the publication of the experiments above alluded to by Dr. Sanderson, I have heated flasks, sealed in the ordinary way and containing the fluid above mentioned, to a temperature of 105° C. for ten minutes in a chloride of calcium bath, and have found these fluids swarming with Bacteria after six days. I have also heated in the same manner simple neutralised turnip-infusion (filtered through cotton-wool instead of filtering paper) to a temperature of 105° C. for ten minutes, and by subsequently keeping these less putrescible fluids at a higher temperature (about 35° C.) they became turbid and swarmed with Bacteria in three days. Neither Dr. Sanderson's experiments nor those of Mr. Lankester and Dr. Pode have, therefore, the cogency which Mr. Lankester imagines them to possess. But, as I have endeavoured to point out on a previous occasion (NATURE, vol. viii. p. 548), experiments of this kind at the present stage

of the controversy can teach us nothing definitely as to the death-point of Bacteria and their germs, though they are of interest with regard to the question of the degree of heat which suffices to check the productivity of the fluids in question.

We are now told that Mr. Lankester himself, and those with whom he sides, are agreed as to the fact that Bacteria are killed at "a temperature a little below 70° C." Of course I cannot tell to what extent Mr. Lankester is in possession of the views of Prof. Huxley and others, but if what he states is really true, the statement is of a reassuring nature; it looks like progress, and leads me to hope that the only remaining doubt may soon be solved. How long does it take for the "through-heating" of certain "possible" Bacteria germs? This is now the knotty problem which, according to Mr. Ray Lankester, seems alone to require solution before we can positively decide as to the heterogenetic origin of Bacteria. Perhaps I may help him on his way to the solution of this difficulty by calling his attention to certain experiments made in Calcutta by Dr. Timothy Lewis, in reference to the existence of living tape-worm germs in cooked meat ("Report of Sanitary Commissioners with the Government of India, 1871"). Dr. Lewis says:—"The temperature of legs of mutton which had been put into the boiler almost as soon as the water was put into it averaged 140° F. (60° C.) in the interior at the moment the water had reached the boiling point (212° F.), and after boiling for five minutes the temperature had reached 170° F. (76° C.)." Now with these facts in his possession, and with some suggestions from physicists of his acquaintance as to the mode of conduction of heat generally, Mr. Lankester may perhaps soon solve his problem, so far as this is practicable. The problem itself may be stated thus:—If the through-heating of several pounds of protoplasm in the shape of a leg of mutton, when immersed in water, takes place at such a rate as to raise the central portions of the joint to a temperature of 60° C. by the time the water has reached 100° C., and if the exposure of the leg of mutton to this heat for the space of five minutes suffices to raise its central portions from 60° to 76° C., how many seconds, minutes, or hours will it take to heat an infinitesimal part of a grain of protoplasm (all through) to the temperature of 76° C.—that is, to a degree of heat decidedly above the death-point of bacterial protoplasm as given by Mr. Ray Lankester? The Bacterium-germ in question, it must be recollected, cannot be supposed to have undergone any extreme amount of desiccation previous to its immersion in the experimental fluid, since such desiccation would have already destroyed its life, according to Dr. Sanderson.

Whilst Mr. Lankester is seeking the solution of the problem above stated, perhaps he might with advantage also reflect a little more closely upon the possible value or otherwise of some of the negative results to which he is so fond of alluding. It is perhaps scarcely necessary for me to remind Mr. Lankester that the obtaining of such negative results is always easy, and may show nothing more than the relative incapacity of the experimenter for performing careful work according to instructions. Not long ago Mr. Lankester, upon the strength of his own negative results, triumphantly announced that he was about to prove to the world the falsity of my views, and so help to justify the opinion which he at the same time expressed as to my being "the mesmerised victim of delusion," "an abnormal psychological phenomenon," and many other fine things. But unfortunately for Mr. Lankester, just about the same time Dr. Sanderson (whose opinions he so much respects) had an opportunity of satisfying himself that I could demonstrate the experimental results which Mr. Lankester failed to obtain. Dr. Sanderson helped to show, in fact, that my positive results were worth more than the many negative results obtained by other workers.

Finally, I think it necessary to add a few words concerning the views of my colleague, Dr. Sanderson, on the subject of heterogenesis, simply because I find his experiments and supposed views frequently quoted by Mr. Lankester, and others, as evidence of the erroneous nature of my conclusions.

I have been led by my experiments to believe in Heterogenesis and also in Archebiosis, but I regard the recognition of the present occurrence of Heterogenesis as of far more importance than the recognition of Archebiosis. Now the controversy between Needham and Spallanzani, and also that between Pasteur and Pouchet was as to the present occurrence or non-occurrence of heterogenesis. This was what they understood, and what the majority of people at the present day still understand, as "Spontaneous Generation." And as to the reality of this process, Dr. Sanderson has been convinced. He admits that Bacteria may appear in flasks, and other situations, where we are warranted in believing that no bacterial matter pre-existed—which is exactly equivalen to a belief in "Spontaneous Generation," in the sense implied by Pasteur and others. In support of this statement I have only to make the following quotations from his papers and reported speeches of the last two years. Referring to experiments made in 1871, Dr. Sanderson says: "Bacteria could not be shown to be present either actually or in germ in the healthy liquids or tissues, or in the products of healthy inflammation" (*British Medical Journal*, May 11, 1872, p. 508). This statement was made with reference to man, and also to the lower animals with which he had experimented. In another part of the same communication as it stands revised in the "Transactions of the Pathological Society," for 1872, Dr. Sanderson says: "If a few drops of previously boiled and cooled dilute solution of ammonia are injected underneath the skin of a guinea-pig, a diffuse inflammation is produced, the exudation liquid of which is found, after twenty-four hours, to be charged with Bacteria." Other chemical agents will act in the same way even when every precaution against external contamination has been adopted; and as a drop of this fluid introduced with equal care into the peritoneum of another animal is always capable of exciting the phenomena of pyæmia, Dr. Sanderson has made known the very important fact that this process "can be proved to be capable of originating from inflammations produced by chemical agents *under conditions which preclude the possibility of the introduction of any infecting matter from without.*" Again, in a speech delivered last month before the Clinical Society, and reported verbatim in the *British Medical Journal* for March 24, Dr. Sanderson insists upon the complete establishment of the truth of this latter proposition both for man and the lower animals. He says: "We must admit that the whole process of pyæmia can originate in the organism independently of external influences." But, as he also says: "In every pyæmic inflammation—whether it be a primary or a secondary one—in every form of pyæmic action, you have always the presence of septic products," that is of Bacteria. Now if Bacteria by their germs do not normally exist in the tissues of animals, and if you can determine their presence there at will under conditions which, as Dr. Sanderson says, "preclude the possibility of the introduction of any infecting matter from without," what must be the mode of origin of the Bacteria in such cases, and how can Dr. Sanderson do other than yield his assent to the doctrine of "Spontaneous Generation," or Heterogenesis, so far as the origin of Bacteria is concerned?

University College, April 6 H. CHARLTON BASTIAN

Earthquake in St. Thomas

ON the morning of the 11th instant at 4.30 A.M., a smart shock, accompanied by a rumbling noise, like that of a waggon rolling over rough pavement, travelling, as is usual here, from east to west, woke up the inhabitants of St. Thomas. It was followed within a few seconds by another shock, to the full as abrupt in its character as the first; the movement appeared to be not so much undulatory as vertical.

The concussion produced was felt still more distinctly within the harbour itself, where the jar communicated to the ships resembled, as one of the captains described it, that which might be produced by a heavy bale falling through the hatchways into the hold. Simultaneously the water of the bay, then perfectly still, assumed a turbid appearance, as though clouded by mud and sand; and a little later the surface was agitated by a strong ripple from the south, lasting some time.

On the same morning early the royal mail steamer *Corsica*, commanded by Capt. Herbert, was at anchor discharging cargo off the harbour of Dominique, about 170 miles distant from St. Thomas, S.E. The harbour is on the side of the island, and sheltered from the swell produced by the trade winds; the weather calm. Just about 5 A.M. a succession of heavy rollers broke in; they lasted for half an hour, and rendered all communication with the shore during that space impossible. No shock was felt on board the *Corsica*, but Captain Herbert caused note to be taken of the marine phenomenon, not doubting that it must have been due to an earthquake, as indeed was evidently the case.

The centre of disturbance would appear to have been in this case under the sea at some distance S.E. from St. Thomas, a direction often indicated in such occurrences. On one occasion only, that of the severe shock of November 1867, did the movement seem to have been propagated from due south, its centre

being in the deep soundings between the islands of St. Thomas and Ste. Croix.

During the same day two other slight shocks, one at about 10 A.M. the other at noon, were felt at St. Thomas; they were unaccompanied by noise. W. G. PALGRAVE

St. Thomas, W. I., March 21

Physical Axioms

CONVINCED that the fulfilment of astronomic predictions can never *demonstrate* the laws of motion, and yet feeling myself quite destitute of intuitive belief in those laws, I have been led to think that in the present controversy truth may lie somewhere between the positions respectively enunciated by Mr. Spencer and his critic.

By reasoning which seems to me equally lucid, ingenious, and unanswerable, Mr. Spencer has shown that certain ultimate mechanical laws are tacitly assumed in every process of experimental verification. But I do not see that this vitiates *completely* the inference drawn from such verifications. The pure empiricists argue that because certain observed results coincide with the results of calculation, therefore the assumptions on which the calculation was based must be true. Now without doubt the *demonstrative* character of this inference vanishes entirely under Mr. Spencer's searching criticism. But it seems to me that a *high probability* remains behind. For were there any but an excessively minute error in the laws of motion, our astronomical observations could agree with the results of calculation only by a conflict of errors—a conflict which Mr. Spencer himself hints at. But there are overwhelming chances that these errors would not be so accurately adjusted throughout an immense variety of cases as exactly to compensate one another in every single instance. Hence I cannot but regard the laws of motion as hypotheses, the truth of which is shown by experiment to be overwhelmingly probable. The doctrine here assumed may be illustrated by an appeal to those old friends of probability students—the dice. If I throw double sixes ten times running I naturally conclude that the dice are loaded. This supposition almost necessarily involves the sameness of the ten throws, whereas the supposition that they were not loaded is consistent with an immense number of other results. Our minds choose the former alternative in obedience to an instinct which might with much show of propriety be formulated into an axiom. We may, however, deduce a justification for it from two ultimate intuitions of our nature—belief in uniformity of sequence and the general doctrine of chances—intuitions by which the mind apprehends respectively the ultimate law of knowledge and the ultimate law of ignorance. Belief in any special fact beyond individual experience can be rationally arrived at only by applying the former law to that knowledge which our individual experience furnishes, and the latter law to that ignorance which our individual experience has failed to enlighten.

It is the *approximate* truth of the laws of motion to which I have throughout referred. That there may be an *excessively minute* error in all physical and even all geometrical principles, Prof. Clifford has long ago shown how unphilosophical it is to deny.

Royal College of Chemistry, April 18

The Fertilisation of Fumariaceæ

Apropos of the interesting discussion on this subject which has appeared in your columns, I should much like to know whether any of your readers have observed the mode of fertilisation in *Corydalis claviculata*. Last summer I spent a considerable time in attempting to find this out, but without success. In every flower which I gathered in the mature state, I found the style broken off at the articulation immediately above the ovary, as if to prevent the possibility of fertilisation after a certain period. As the interior parts are completely concealed by the corolla, it was difficult to determine whether the separation had actually taken place on the flower, or was the result of the dissection, but I believe the former to be the case. In a large number of observations, extending over a considerable time, I never saw an insect visit the plant (this was in Westmoreland), though seeds were freely produced. Müller does not mention this species in his classical work on the subject, "Die Befruchtung der Blumen durch Insekten." ALFRED W. BENNETT

ALLOW me to bring before the notice of readers of NATURE a small point bearing on the fact of the bright hue presented, after fertilisation, by the flowers of *Fumaria capreolata*.

Is it not possible that the pale colour may be more attractive to the fertilising insects than a brighter one would be? May not the drawing-principle be the result of correlation between the art-manifestations of the attracting and the æsthetic susceptibilities of the attracted organism, and not depend solely on gaudiness of the flower? If this be so, we know that these susceptibilities have, at any rate sometimes, a very limited range, as is seen in the bee-orchis, where the similarity of the labellum to the body of a bee is very close, both in colour and in form, and cannot be useless, seeing that a great amount of developmental force is expended in its production. On this view also the rejection of highly-coloured poisonous caterpillars may in part be referred to the non-agreement of their hues with the orthodox colour-notions of birds. On the other hand, if mere gaudiness is aimed at, why should there be such diversity exhibited? why would not one colour answer the purpose in every instance?

The present case is capable of ready explanation on the supposition that it comes under the influence of natural selection; for, as Mr. Spencer has shown, the hue of the flower results from a diminished amount of nutritive material supplied to the coloured parts, so that the least vigorous individuals would have these most highly coloured at the time of fertilisation. But since the pale flowers are preferred by the insects, they would stand a better chance of being fertilised than would the bright ones, so that a process of selection would be set up resulting ultimately in the disappearance of the latter.

If it be established that cross fertilisation is not the rule with the flowers of this fumitory, of course it is a fact which has nothing whatever to do with the present argument, and the explanation given by Messrs. Darwin and Müller is entirely satisfactory. I cannot but think, however, that special attention will bring to light many cases of cross-fertilised flowers becoming more highly coloured after fertilisation, the phenomenon being explained simply as a decomposition-phase in the life-history of the contents of the cells composing the coloured organs.

S. MOORE

I VENTURE to suggest the following as possibly an explanation of the fact observed by Mr. Traherne Moggridge, that the flowers of *Fumaria pallidiflora* attain their brightest colouring when the time for their fertilisation has past.

In plants with a racemose inflorescence the individual flowers do not open simultaneously, but more or less in succession. The flowers lowest in the raceme open first: by the time they have in *Fumaria pallidiflora* attained their brighter colour, those a little higher up on the rachis are just at the stage for fertilisation, and the former may serve to attract insects to the latter, just as in some plants (*e.g.* Poinsettia) we may presume that the highly-coloured bracts attract insects to the comparatively inconspicuous flowers which they surround. The flowers a little way up the raceme would serve in their turn to attract insects to those above them; and these again to those still higher; the process going on for a considerable time in Fumaria, as it is quite common for the pedicels in the lower part of a raceme to be bearing fruit that has attained its full size, while at the top there are flower-buds still unopen.

Quisqualis indica affords another instance of flowers assuming a more intense colour after fertilisation. Its flowers grow in short spikes; on first opening and during fertilisation, are white, very faintly tinged with pink; but subsequently turn a light reddish-orange, and finally a purplish-red. T. COMBER

Newton-le-Willows, April 7

Power of Memory in Bees

ILLUSTRATIONS drawn from experiments or observations made upon animals lower than ourselves in the scale of life must always possess great interest. That impressions received by us in early life are more permanent than those made in after years, and that the memory of the old is less retentive in the reception of new impressions than is that of children, are circumstances universally acknowledged. On October 29, 1873, I removed a hive of bees in my garden, after it was quite dark, for a distance of 12 yards from the place in which it had stood for several months; and between its original situation and the new one there was a bushy evergreen tree, so that all sight of its former place was obstructed to a person looking from the new situation of the hive.

Notwithstanding this change, the bees, every day, flew to the locality where they formerly lived, and continued flying around the site of what had been their home, until, as night came on, they many of them sank upon the grass exhausted and chilled by the cold. Numbers, however, returned alive to their new position,

after having looked in vain for their hive in its old place. At night I picked the exhausted bees up, and, having restored warmth to them (by leaving them for a time upon my coat-sleeve), I returned them to their companions.

Here was an illustration that the faculty of *memory* was superior to that of *observation*; but that was not all. Nearly every bee which I picked up during the twenty-three days through which this effort of memory lasted was an *old one;* as was easily deduced from observing the worn edges of the wings: showing that, whilst the young insects were quick in receiving new impressions, and in correcting errors, the nervous system of the old bees continued *acting in the direction which early habit had affected.* So true is it that "One touch of *Nature* makes the whole world kin."

Marlborough House, Torquay JOHN TOPHAM

Pollen-grains in the Air

WILL you allow me to ask Mr. Hubert Airy, in reference to his interesting paper on the "Microscopic Examination of Air," in NATURE, vol. ix. p. 439, on what ground he refers the "triangular pollen" captured on his slide to the birch and hazel? Observations of my own have led me to the conclusion that the pollen of plants which depend exclusively on the wind for their fertilisation is perfectly spherical, at all events before the form of the grain is disturbed by the emission of the pollen-tubes, and this indeed one might expect from *à priori* considerations. Among the pollen-grains I have especially observed, are those of *Corylus avellana*, *Betula alba*, and *Populus balsamifera*. I shall be much obliged if any of your readers could refer me to any accurate published description of the form of pollen-grains beyond those contained in Fritzsche's "Beiträge zur Kenntniss des Pollen." Lakes with two Outfalls

I AM a little surprised to find, by the recent letters in your paper, that Science makes so wide a mouth over this phenomenon, though its exceptional character, and the general correctness of Colonel Greenwood's theory, must readily be recognised. My surprise is occasioned by the fact that Norway, which is now visited by thousands of educated English tourists every year, can supply, not one, but several, I had almost written many, apparent examples of this double outflow. I have not myself passed the watershed at the Lesjeskaagen Lake, though I was close to it in August last, and would have examined it if I had known its importance; but I know enough of the locality to think that Colonel Greenwood is probably right in his explanation of it. But there is another, which I have passed, and which is situated on perhaps the most frequented route in Norway, viz. that from Lærdalsören over the Fille Fjeld, to which I hardly think the same explanation would apply. Between Nystuen and Skogstad is a chain of lakes crossing the watershed, the highest of which (not the one marked on the Vei-cart over Norge, I think) sends its waters to the west, past Nystuen to the Sogne Fjord, at Lærdalsören, and on the east by the Lille Mjösen, and Aadalen to the Tyrifjord, and so past Drammen to the Christiania Fjord. This lake is a small one, and the double outflow is close to the high road. I cannot imagine any commercial object for an artificial cut, and it must be well known to hundreds who annually pass it. The Vei-cart shows several other instances, I know not how authentic, though I have always found it fairly accurate, erring rather by omission than commission. But in lat. 62° N., long. 24° 40′ E. or thereabouts, is a very remarkable watershed, having a complication of outfalls; the Bredals-Vand sending one to the N.W. to the Geiranger Fjord, and a second to the Vaage-Vand and Gudbrandsdalen; which is also joined by a draft from a lake to the S.W., which likewise sends a feeder to the Opstryen Vand, and so W.S.W. to the Nord Fjord. This I have not myself seen, but I was at Merok on the Geiranger for some days last August, and was assured by my landlord that the map was correct in this particular. As the Norwegian peasantry are well-educated, intelligent, and truthful, and this route forms their regular short cut to Christiania, I cannot doubt but that it is the fact. However, I have engaged to go over the track this summer with Captain Dahl, the well-known jolly commander of the *Erknö*, and I will take care to ascertain the truth and report the result. If, moreover, there are any geological or geographical points to be attended to, and Colonel Greenwood will kindly furnish me with instructions, I shall be happy to attend to them.

I have a strong recollection of having passed two or three cases of double outfall on a small scale in my wanderings; but not having been aware of the importance of the point, I did not take notice sufficiently precise to enable me now to put my finger on them with certainty, but my general conviction is strong, that Norway can furnish several, if not many examples, which are the more significant from the fact that it is one of the oldest countries in the world. W. B. THELWALL

Burghley Road

WILL you permit me to correct a mistake as to a matter of fact in NATURE, vol. ix. p. 441. Loch-na-Davie, Arran, has two outlets, as is correctly represented in the Ordnance Map, and also in that in Bryce's "Geology of Arran." In August 1872 I walked up the north stream from Loch Ranza to its outfall from Loch-na-Davie. I think Colonel Greenwood ought at least to have made himself acquainted with the Ordnance Map.

IV.

TRISTAN D'ACUNHA

AMONGST the places in the Atlantic marked out by the Circumnavigation Committee as being of especial interest, the small island of Trinidad is noted with those whose vegetation is absolutely unknown, or all but so. From this fact Trinidad became a point of attraction which Mr. Moseley was most anxious to reach. Owing, however, to unfavourable winds and other causes, as well as to a desire of those in command of the ship to proceed south, the visit to this little island was abandoned, with the hope of calling there on the return voyage. After a narrow escape, also, of missing Tristan d'Acunha, the vessel anchored on the north side of the island, and the morning was spent in searching the low lands under the cliffs, 500 feet being the greatest height that was attained during the stay. On this side the island rises in a range of perpendicular cliffs of black volcanic rock, in appearance somewhat similar in structure to that exposed in section in the Grande Cural in Madeira. At the base of the cliffs here are *débris* slopes, and a narrow strip of low shore land of an irregular rocky and sandy nature. The settlement lies on a stretch of low land, broader and more even, and extends westward. The ascent to the plateau above the cliffs is comparatively easy, owing to the deep gullies by which the cliffs are broken.

Though the extent of the island is small, its actual area being not more than 16 square miles, the botanising was confined to the irregular strip of shore land just alluded to, and to the gully immediately above the settlement. Further exploration would have been made, but a sudden squall coming on, the recall was hoisted from the ship, and the party had to leave the island, after a visit of only six hours. Grasses, sedges, mosses, and ferns grow on the cliffs, and occasional patches of *Phylica arborea* Th., a rhamnaceous tree peculiar to the islands, as well as a species of *Empetrum*; these plants, however, are more prominent towards the summit. At the foot of the water-courses under the cliffs are bright green patches of *Rumex frutescens* Th. Mosses and liverworts cover the lower part of the cliffs, and the latter also abound beneath the grass in some situations to such an extent, indeed, as to cover the earth as with a green sheet. *Spartina arundinacea* Carm., grows in rounded tufts amongst the other herbage, and in the clefts of the rocks was seen in abundance *Asplenium obtusatum* Forst., and *Lomaria alpina* Spreng. It is remarkable that the plants of *Lomaria* when found in stony places, and in a comparatively starved condition, were mostly furnished with fertile fronds, whilst those growing in rich vegetable mould were barren. Amongst flowering plants the most common were *Apium australe* Th., *Pelargonium australe* Jacq., *Sonchus oleraceus* L. our common annual sow-thistle, *Hypochæris glabra* L. a closely allied plant to the sow-thistle, and also found in many parts of England. A cinchonaceous plant, *Nertera depressa* Banks, was very abundant, and

* These Notes are founded on letters sent home by Mr. H. N. Moseley. Continued from p. 451.

Oxalis corniculata L., with its yellow flowers, was likewise seen, but not in any quantity.

An interesting plant—*Chenopodium tomentosum* Th.—grows abundantly on Tristan as well as on Inaccessible Island; it is known as the tea plant, and the leaves, which are strongly scented, are used for making a decoction which is drunk with milk and sugar.

In the gully above the settlement, shrubs of *Phylica arborea* commence at an elevation of about 400 ft. No trees are found in this locality, having all been cut down at different times for fire-wood, but on other parts of the island there is abundance of wood. The diameter of the trunks of the trees on the upper plateau, it is said, reach to 18 in. On some fresh-water ponds close to the sea was a quantity of confervæ, but no chara was seen, a species of *Isolepis* also grew on the edges of these ponds which was not seen on the other two islands. A few willow bushes grew in a sheltered situation in a ditch near the cottages, and seemed to be thriving. Growing round the island is a belt of *Macrocystis pyrifera* Ag., a gigantic sea-weed, abounding in the southern temperate zone, and stretching up from thence along the Pacific to the Arctic regions. It occurs in immense lengths, single plants of from 100 to 200 ft. being common, and it is said that they are sometimes seen from 700 to 1,000 ft. in length, forming cable-like masses nearly as thick as a man's body, and having the appearance of huge buoys.

The surf on the rocky coast of Tristan is so heavy that the more delicate sea-weeds stand no chance, but are dashed and torn into numerous pieces.

The temperature of the fresh-water ponds at the sea-level gave a result of 54° F. while the water of the streams running down the cliffs stood at 50°, the difference being due evidently to the influence of the snow-water from above.

FUNERAL OF THE LATE DR. LIVINGSTONE

ON Saturday last the remains of David Livingstone, which left Central Africa now nearly a year ago, were interred in Westminster Abbey, in presence of a multitude such as was probably never collected therein on any similar occasion. The funeral procession, which started from the Geographical Society's Rooms, Savile Row, was of great length, though of the plainest description possible under the circumstances; we have not learned whether this was in accordance with the wishes of the late traveller's relatives, or whether it arose from scarcity of funds. Every mark of respect was shown to the procession along its route, and at several advantageous points considerable crowds had collected to witness the last journey of the great explorer.

Men of all ranks and of all pursuits in life formed part of the procession, and stood around the grave during the service in the Abbey. The patriarchal Dr. Moffat, Livingstone's father-in-law, and the traveller's two sons, Thomas and Oswell Livingstone, Mr. James Vavasseur, Sir F. Steele, Dr. Kirk, Mr. W. F. Webb, the Rev. Horace Waller, Mr. H. M. Stanley, Mr. E. Young, Sir W. Fergusson, the Duke of Sutherland, Sir Bartle Frere (President of the Royal Geographical Society), Sir H. C. Rawlinson, Vice-Admiral Baron de la Roncière le Noury (President of the French Geographical Society), Dr. Hooker (President of the Royal Society), Mr. C. R. Markham, Mr. R. H. Major, Mr. H. W. Bates, Dr. Houghton, Mr. J. Young of Kelly, are the names of some of those who followed the body to the grave; there were besides, deputations from Edinburgh, Glasgow, and other places, and the carriages of Her Majesty the Queen, the Prince of Wales, and of many other noble and distinguished persons formed part of the procession. Among those who were waiting inside the Abbey were men of every shade of thought, political and religious, men distinguished in every walk of life, deputations from many religious bodies, from the establishment outwards, and representatives of various scientific Societies. The bearing of the crowds both outside and inside the Abbey showed that they were brought together from genuine admiration and sincere respect for the memory of the simple-minded hero.

We think the character of the assemblage which gathered to do honour to Livingstone's remains is one proof that he has done a work calculated to call forth the admiration and gratitude of those whose suffrages constitute fame of the highest and most enduring kind. If to conceive a great and noble purpose and to carry it out even unto death, with indomitable energy, determination, and the greatest skill, in the face of every possible discouragement, discomfort, and obstacle, be a mark of greatness, his contemporaries have certainly made no mistake in raising David Livingstone to the lofty pedestal which he at present occupies. He has probably added more largely to the sum of exact geographical knowledge than any other explorer has hitherto done. As Dean Stanley eloquently said in his funeral sermon on Sunday afternoon:—"By his indomitable resolution we have now revealed to us, for the first time, that vast tract of Central Africa which, to the contemplation of the geographer, has been literally transformed from a howling wilderness into the glory of Lebanon. The blank of unexplored regions which in every earlier map formed the heart of Africa is now disclosed to us adorned with those magnificent forests, that chain of lakes 'glittering'—to use the native expression—'like stars in the desert;' those falls more splendid, we are told, even than Niagara, which no eye of civilised man had ever before beheld. And to his untiring exertions, continued down to the very last efforts of exhausted nature, we owe the gradual limitation of the basin within which must at last be found those hidden fountains that have lured on traveller after traveller, and have hitherto baffled them all."

A deputation of gentlemen interested in the family of the late Dr. Livingstone waited on Monday upon the Chancellor of the Exchequer and the Secretary of State for Foreign Affairs, for the purpose of representing to Her Majesty's Government the very general anxiety that was felt throughout the United Kingdom that some substantial recognition, in the shape of an adequate provision for his family, should be made of the services of the great traveller. A requisition to the Prime Minister, asking him to confer a pension on the family of Dr. Livingstone, was on Monday night circulated among members of Parliament at the House of Commons. A large number of signatures has already been attached by gentlemen on both sides.

About three years ago, Her Majesty, at the recommendation of Mr. Gladstone, conferred a pension of 300*l.* a year upon Dr. Livingstone, who, however, it is sad to think, never knew that his services had been so recognised by the Government. Upon the death of Livingstone the pension ceased, but it was deemed by Mr. Gladstone a matter of sheer merit, due to the great explorer, to confer some pecuniary benefit upon his children, and the figures on the civil list were thereupon reduced from 300*l.* to 200*l.*, which is actually the amount that will henceforth be paid by the Government to those he has left behind him. Though Dr. Livingstone made a large sum of money out of the first book he published, still he disbursed more than half that amount in his promotion of the exploration of the Zambesi.

Livingstone's devotion to the cause of science and of philanthropy has thus been the means of leaving his family very inadequately provided for; but as he has added so greatly to the glory of his native land, and as he spent his life in the service of civilisation, we feel confident that those for whom he was therefore unable to provide will be well cared for.

From a letter in yesterday's *Times* we see that the Diary kept by Jacob Wainwright for nine months after Livingstone's death will shortly be published.

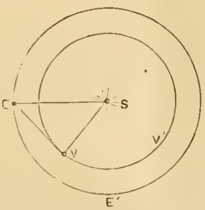
THE COMING TRANSIT OF VENUS *

II.

THERE is perhaps no problem which has been so constant a source of interest to the learned in all ages as the solving of the mystery of the solar system. The labours of Copernicus, Tycho Brahé, Kepler, and Newton have given us a general knowledge of the nature of the planetary motions; and the investigations of later mathematicians have enabled us to predict, with wonderful accuracy, the future positions of the planets. But the dimensions of the solar system are not known with the same precision.

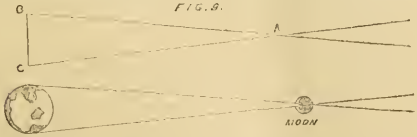
It is true that we know the *relative* distances of all the planets from the sun with tolerable exactness. This problem has been attacked in two totally different methods. The first is by measuring directly the changes that are

FIG. 8



produced in the motions of the planets when the earth has moved through a certain portion of its orbit. In the case of the planets Mercury and Venus, which move in smaller orbits than that of the earth, the direct observation can easily be made. For let us suppose VV′ and EE′ (Fig. 8) to be the orbits of Venus and the earth, and S to be the sun. Let us watch the position of Venus night after night until she is as far away from the sun as possible. If we measure her apparent distance from the sun by astronomical means, we shall know that the sun, Venus, and the earth occupy positions such as S, V, and E; the directions ES and EV being known from our observations. By measuring off the distances SV and SE on the diagram, we actually find the relation between the earth's distance from the sun and that of Venus. The same can be done with Mercury; but for the superior planets the direct mode of observation is more difficult.

FIG. 9.

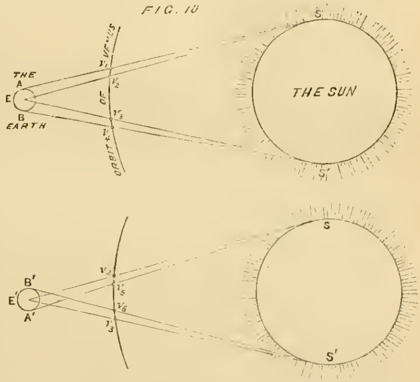


But there is an indirect method which is much more easy to apply. Kepler's three laws have been shown to be necessary consequences of Newton's theory of gravitation. Now Kepler's third law tells us how to find the relative distances of two planets from the sun when we know the relation between their periods of revolution. The exact law is this:—Multiply the number of years taken by a planet to go round the sun, by the same number. This gives us a first number. Then find a second number which, multiplied by itself twice, gives us the first number; this second number is the distance of the planet from the sun (the earth's distance being called 1). To take an example: Jupiter takes about 11 years to go round the sun; 11 multiplied by 11 gives us a first number, 121. Now if 5 be multiplied by 5 we get 25, and if this be again multiplied by 5 we get 125, which is almost the same as the first number, 121. Hence we are right in saying that Jupiter is about five times as far from the sun as the earth. If we had used the exact number of years we should have got the exact distance. Now it is very easy to find the period of revolution of a planet. For we can easily measure the interval between two dates when Jupiter and the earth, for example, are in the same line with the sun; in other words, we can measure the "synodical revolution" of Jupiter; and from this it is easy to calculate the time of Jupiter's revolution round the sun.

By applying these methods to all the planets we can lay down their orbits upon a plan; *all we wish now is to find the scale upon which our plan is drawn.* If we knew the distance of the earth from the sun, or if we knew the distance between any two of the planetary orbits, we should know the scale upon which our plan is laid down. Various methods have been adopted for this, but the one which makes use of a transit of Venus has generally been considered to be the most accurate.

One method which has successfully been applied to measuring the moon's distance is that used by surveyors. The surveyor chooses two spots, B, C, whose distance he measures. Suppose it to be one mile. He draws this distance, say, to one inch on a sheet of paper. He then

FIG. 10



takes a telescope, mounted so as to enable him to measure any angle through which it is turned. He places the telescope at B, pointing towards C. He then turns it till it points at the distant object, and finds what the angle of B is. He then draws the line BA upon the paper, and he knows that the distant object lies somewhere on the line BA. He then does the same with C, and thus he knows that the remote object lies on CA. But A is the only point lying both on BA and CA; hence A corresponds to the distant object. If on measuring CA he finds it to be 30 inches, then since CB, which is 1 inch, means one mile; CA, which is 30 inches, means 30 miles, and this is what he wanted to find out.

If, instead of taking a base-line (as it is called) of one mile, the diameter of the earth, or 8,000 miles, be taken; then, if the moon be the distant object, we can determine its distance in almost the same way. It is in this manner that the moon's distance has been measured. It is easy to see that if the angle at A (Fig. 9) were very small, a slight error in measuring either of the angles B or C would make a great difference in the distance deduced for the remote object. Hence, if the moon's parallax were very small, this method would be unsuitable. But the parallax of the sun is very small, and

* Continued from p. 419.

hence we cannot find the sun's distance with any exactness by this method.

But if any one of the planets ever came so close to the earth as to make its parallax tolerably large, then we could determine the scale upon which the solar system is built up. Now Venus and Mars are two planets which at certain times come closer to the earth than any other planet. But, unfortunately, when Venus is most near to the earth she is generally invisible, because the whole of her illuminated side is turned away from us. Mars, however, is a planet that gives us a very favourable opportunity for determining its distance. The advantage is increased by this peculiarity, that every fifteen years Mars is at its shortest distance from the sun, at the same time that the earth is at its greatest distance, the two planets being also in the same line with the sun, so that they are closer than we might have thought possible. In fact, on these occasions Mars is nearer to the earth by $\frac{1}{25}$th part than she is if the conjunction take place when both the earth and Mars are at about their mean distances from the sun. Suppose then that under such circumstances two observers, one at Greenwich and the other at the Cape of Good Hope (where there is a fine observatory), observe the position of Mars as compared with that of a star at the same time. The position of Mars will be displaced by parallax; and by comparing the apparent distance of the planet from the fixed star at these two places we can find the sum of the parallaxes in these cases. Hence we can find the distance of Mars, as already explained.

This was the first method to give a value of the solar parallax with anything like accuracy. At the suggestion of Cassini, the French sent out an expedition to the Cape, under the astronomer Picard. The value obtained for the sun's parallax was 9″·5. Prof. Henderson in 1836, and Mr. Stone, in 1862, utilised this method. Another opportunity will occur in 1878.

Before proceeding to the method of the Transits of Venus, it will be well briefly to allude to some other methods by means of which the solar parallax, or the sun's distance, has been estimated.

It has been found that light takes a sensible time to propagate itself through space. Hence, when one of Jupiter's satellites passes into the shadow of the planet, this fact is not communicated to our vision for something like 38 minutes, the time taken by light to pass from Jupiter to the earth. Now, when we are on the same side of the sun as Jupiter, this distance is shorter by the whole diameter of the earth's orbit than when we are at the opposite side of the sun. Hence, in the former case, the eclipses will seem to take place sooner than the predicted time, and in the latter case later. The difference in either case is about 8 minutes, and as we know that light travels over 298,500 kilometres per second,* this tells us that our distance from the sun is about 91,000,000 miles.

But our knowledge of the velocity of light has been utilised in another manner to solve the same problem. You see that if we know the earth's velocity in miles, we can find its distance from the sun. For if it goes $1\frac{1}{2}$ million miles in one day, it must go over 365 times that in a year, and *that measures in miles the circumference of our earth's orbit*, and hence we can get our distance from the sun. How then are we to find the velocity of the earth in miles. This depends on a curious property of light. In a steady down-pour of rain you hold your umbrella upright if you are standing still, but incline it forward if you are walking fast. This is to make the umbrella catch the rain-drops. The amount of inclination you give it depends upon the rate at which you are walking compared with the velocity with which the drops fall. The same thing happens with light. We have to incline our telescopes forward a little in the direction in which the earth is moving to catch the rays of light; and at opposite seasons of the year the earth is moving in contrary directions, and the telescope has to be pointed in sensibly different directions. The inclination that a telescope receives is known, and the velocity of light being known, we can find the velocity of the earth, and hence, as I have shown, the distance of the earth from the sun.

There is another method of peculiar interest depending upon the motions of the moon. The law of gravitation says that the attraction of each body for each other one depends upon the distance between them. The moon is attracted to the earth by a force, depending upon the distance of the moon, which is known in miles. But the moon is caused to deviate from its natural course on account of the sun's attraction. This depends upon the distance of the sun from the earth, and if this be not known exactly in miles we shall see that it is impossible to apply calculation to foretell the motions of the moon; for, if upon any scale we attempt to lay down upon paper the relative positions of the sun, earth, and moon, we shall place the moon at its proper distance, and the sun, though in its proper direction, will not be placed at the proper distance, and we shall not know the direction in which it attracts the moon, nor the magnitude of this attraction, and we shall make our calculation wrongly, and the moon's observed place will differ considerably from its calculated place.

Such a difference was actually detected by the illustrious Hansen, whose tables of the moon are the best we possess. Hansen saw that this must be due to a wrong assumption as to the distance of the sun, and communicated his doubts to the Astronomer Royal * in the year 1854. This led to a re-discussion of our knowledge of the subject which has confirmed Hansen's views, and which leads us to see the importance of knowing accurately the sun's distance, if we wish ever to have our tables of the moon so accurate that we may determine the longitude by their aid. This method for investigating the solar parallax was first used by Laplace.†

More recently, M. le Verrier has suggested a new method that promises in time to be the best.‡ In the lunar theory, an equation appears connecting the relative masses of the earth and sun with the solar parallax, so that if we know the one we can find the other; and from a peculiarity in the equations, a small error in determining the relative masses will affect only very slightly the deduced parallax. Le Verrier finds the ratio of the masses of the earth and sun by determining the effect of the earth's attraction upon Venus and Mars. This being applied to the lunar theory, a value of the solar parallax is obtained.

The method, however, which has found most favour up to the present time, is the employing of transits of Venus to measure the sun's distance. When a transit of Venus occurs, the first evidence of the phenomenon is given by a slight notch being made in the contour of the sun's edge at a certain spot. This notch increases until the full form of the planet is seen. The first appearance of a notch is called the time of first external contact. But when the planet appears to be wholly on the sun, her black figure is still connected with the sun's limb by a sort of black ligament, of which we shall say more hereafter. When the whole of the planet is just inside the sun's edge, the time of first internal contact has arrived. The breaking of the ligament is a very definite occurrence, and was, until lately, taken to indicate the true moment of internal contact. The second internal and external contacts take place as the planet leaves the sun.

In 1663, the celebrated James Gregory, in his famous work the "Optica Promota," *prop.* 87, *Scholium*, alludes

* As determined by Foucault, *Comptes Rendus de l'Acad. des Sciences*, vol. lv. p. 502; also by Cornu, *Comptes Rendus*, Feb. 10, 1873.

* *Monthly Notices, R.A.S.*, vol. xv., Nov. 1854.
† *Système du Monde*, t. ii. p. 91.
‡ *Comptes Rendus*, July 22, 1872.

to the possibility of determining the sun's parallax by means of the transit of an inferior planet. He has been showing methods of finding the parallax of a planet by comparison of observations made at different parts of the earth upon the position of the planet compared with that of a star. He then takes, in place of a fixed star, another planet, the two being in one line, as seen from the earth. The application of this to the case of Mercury or Venus and the sun, was obvious.

But Halley was the first to see clearly what a powerful means of determining the sun's parallax an observation of contact really is. So far as I can discover, he first mentions the method in a letter to Sir Jonas Moore, written at St. Helena in 1677,* just after having seen a transit of Mercury. The exactness with which he believed the time of contact to be determinable, led him frequently afterwards to urge his countrymen to make every effort to utilise the method on the occasion of the transits of 1761 and 1769, when he should be dead.† And thus, in addition to his celebrated prediction of a comet, he left a second legacy to his successors, who, as Englishmen, might be entitled to be proud of his foresight though he could not live to reap the glory of it.

It is a matter of some difficulty to show, in an elementary manner, the way in which the value of the sun's parallax can be found from observations of contact. We will try, however, to put it in a light which anyone, with a little attention, will understand.

1. It must be thoroughly understood, from what has already been said, that if we know the amount of the sun's parallax we know its distance. In other words, if we know the angle subtended by any known distance on the earth's surface at the distance of the sun.

2. We know that the relative positions of the earth, Venus, and the sun, are given by supposing the earth to go round the sun in 365 days, and Venus in 224 days. Or, if we please, we may take no account of the earth's revolution, but suppose it fixed, in which case the revolution of Venus *relatively* to the earth (*i.e.* the synodical revolution) is 584 days.

3. If, then, Venus moves round the sun through 360° relatively to the earth in 584 days, she moves through $\frac{1}{584}$ of that in one day, and through $\frac{360}{584 \times 24}$ of a degree in one hour; which is at the rate of about $1\frac{1}{5}$ seconds of arc in a minute of time.

Now we are ready to understand Halley's reasoning.

Let A (Fig. 10) be the position of an observer on the earth at the time of 1st internal contact. S is the sun, and V_1 is now the position of Venus. This observer sees the contact earlier than a hypothetical observer at the earth's centre would see it, by the time Venus takes to move over V_1V_2. If we knew by calculation the instant when an observer at E would see it, and the observer at A saw it 8 minutes sooner, then, since Venus moves over $1\frac{1}{5}''$ in a minute, she has moved over $8 \times 1\frac{1}{5}$ or $9\frac{3}{5}''$ of arc in this time, and hence we learn that the angle A S E = $9\frac{3}{5}''$.

Suppose that by the time of the last contact the point A on the earth's surface has been carried by her rotation to B: the time of the last contact will now be too late by $8'$; since the whole duration of the transit as seen by this observer is $16'$ too long, and the angle moved over by Venus in $16'$ is the sum of the sun's parallax as seen from A and from B.

But we cannot calculate with absolute accuracy the duration a transit would have when seen from E, because we should require to know more accurately than we do the values of Venus' and the sun's diameters.

Halley got rid of this by taking another station which should be in the position A at the beginning of the transit. In the case we have been considering the time of the first contact would here be too late by 8 minutes; and if this place had reached B′ by the end of the transit, the time of contact would be too soon by 8 minutes. Hence in this case the whole duration would be shortened by 16 minutes; but in the former case it was lengthened by 16 minutes. Hence 32 minutes is the time taken by Venus to pass over an angle equal to the sum of the parallaxes in the four cases considered. This difference of duration, whether it be 32 minutes or anything else, is a quantity which can be observed. Now Venus moves over about $1\frac{1}{5}''$ of arc in a minute, or $38\frac{2}{5}''$ in these 32 minutes. Hence one-fourth of $38\frac{2}{5}''$ or $9\frac{3}{5}''$ would appear, from the above hypothetical observation, to be the value of Venus's parallax.

It must be noticed that we have here supposed that the transit takes exactly twelve hours, whereas the longest transit cannot exceed 8 hours. We have also supposed that two stations had been selected which were exactly situated so as to bring out the full effect of parallax at the time of each observation. These suppositions have been introduced only to simplify the understanding of the method. Anyone who has followed the above explanation will see how the method may be applied to actual cases that may occur.

Halley saw (what many people fail to see even now) that the great accuracy of the method consists in this, that in one second of time Venus moves over about $0''\cdot02$; and if we can determine the time of contact, with an error of no more than a second, we are measuring the sun's parallax with an error of no more than ·02 of a second of arc.

Halley even pointed out the best stations for observation. We may consider the earth to be at rest if we suppose Venus to move with the velocity she has relative to the earth. He supposed that the planet would cross near the sun's centre, and that the transit would occupy about eight hours. An observer in India would see the commencement of the transit four hours before mid-day, and the end of the transit four hours after mid-day. But, in the meantime, the part of the earth where he is has been moving from west to east, and Venus has moved from east to west, hence the duration of transit will have been shortened. But at Hudson's Bay the transit begins just before sunset and ends just after sunrise, that part of the earth having moved in mean time from east to west so as to lengthen the transit; and thus at one place the duration of transit is lengthened, and at the other shortened, and the difference of time depends upon the parallaxes of Venus and the sun * at the two stations, and after finding these parallaxes we can calculate the equatorial horizontal parallax.

GEORGE FORBES

(*To be continued.*)

* Hooke's "Lectures and Collections," 1678.

† "Catalogus Stellarum Australium;" also "Phil. Trans.," 1694 and 5.

* This lengthening or shortening of the time of transit will be rendered more evident by an analogy. A person standing still sees a carriage pass between him and a distant house The carriage will take a certain time to pass the house. But if he be also moving, and in the same direction with the carriage, the transit of the carriage will take longer; but if he move in the opposite direction to the carriage, the transit will take a shorter time. If, then, two persons be seated at opposite sides of a merry-go-round, so that at the time the carriage seems to be passing the distant house, one observer is moving with the carriage and the other in the opposite direction; then one observer will see the time lengthened, and the other shortened Now, the world is such a merry-go-round, and the positions of these two people correspond to the positions of India and Hudson's Bay, as pointed out by Halley.

THE LECTURES AT THE ZOOLOGICAL SOCIETY'S GARDENS

I.

ON Tuesday, April 14, Mr. P. L. Sclater, F.R.S., gave the Introductory of the twelve lectures which are to be continued during the spring. His remarks on that occasion were chiefly confined to the subject of Zoological Gardens in general. After an interesting account of the most important continental gardens, including those of Paris, Amsterdam, Antwerp, Berlin, and Hamburg, he

went on to speak of the different animals which thrive best in captivity, taking each order of each of the great classes of the vertebrata separately, and pointing out that whilst some, as the Carnivora, thrive well in confinement, others, as the Insectivora, can hardly be kept in a menagerie at all.

On the following Friday Mr. Sclater commenced the first of four lectures On the Geographical Distribution of Mammalia. A fauna constituting the animals inhabiting a country, and a flora its plants, the lecturer went on to illustrate the fundamental law that the animals and plants found in far distant countries are usually different, and that those of near countries closely resemble one another. We find the animals in France much like those in England, those in Ceylon much less so, and those in Australia as different as possible. It might at first sight be thought that difference of climate caused the differences that are observed in geographical distribution, but that such is not the case is proved without difficulty by taking different countries in the same latitude and with a similar climate and comparing them. For instance, on and near the equator we have Borneo, part of Africa, and the country bordering the Amazons; nothing can be more different than their faunas, and yet they are similarly circumstanced, so far as temperature and climate are concerned. So the polar seas of the northern and southern hemispheres are very different as regards their animals, although nearly identical in climate. The auks and seals of the one are replaced by the sea lions and penguins of the other. The faunas of the Himalayas and of the Andes, mountains both in hot countries, are very different also.

The meaning of the terms "specific area" and "generic area" was then explained. A species, the aggregate of similar individuals, has an habitat or area of distribution which is definitely circumscribed. In some animals this area is large, as in the case of the lion; in others, as in the case of the aye-aye of Madagascar, it is extremely limited. Among birds this limitation, strange as it may appear, is sometimes extreme; on each of the two nearly adjoining mountains of Pichincha and Chimborazo there are species of humming-birds found, which occur nowhere else. The area which includes all the areas of the species of a genus forms a generic area. These areas are continuous, or were so at one time; physical changes having sometimes intervened to produce an apparent interval.

From these observations it is evident that the locality in which an animal is found is as important a fact in estimating its individuality as are its internal structure and general configuration. This point is frequently but too little taken into account.

The lecturer, having said thus much on the general subject, proceeded to show how the class of Mammals was to be distinguished from the other classes of Vertebrates, and stated that for geographical purposes the mammalia, or those animals which suckle their young, might be most conveniently divided into terrestrial and aquatic. Our knowledge respecting the former of these sections is, as might be imagined, much greater than of the latter; nevertheless, within the last few years the aquatic mammalia have received considerable attention, and have become much better known.

(*To be continued.*)

NOTES

THE magnificent bequest of 10,000*l*. has been made by the late Mr. E. R. Langworthy to the Owens College, Manchester, for the purpose of developing the chair of Experimental Physics. A splendid opportunity is thus afforded to the Professor of Physics in Owens College not only to advance original research in connection with that subject, but also of teaching the students of his class in the only effectual way by which physics can be taught. Physics, in short, can now be placed on the same footing in that University as chemistry. The terms in which the bequest is made are so forcible and clear that they deserve to be quoted here:—"I bequeath to the trustees of the Owens College ten thousand pounds, and I desire that the same may be applied by them as they may think best in order to establish in connection with that institution a professorship of Experimental Physics. It being my wish that students may be instructed in the method of experiment and research, and that Science may be advanced by original investigation. And I also desire that the professor from time to time appointed may be selected on account of his knowledge having been especially obtained by original investigation, and that his appointment shall be contingent upon the continuance of such investigation. And I declare that the above desire shall not be construed as a trust and bind the trustees to establish a professorship; but in case it shall be deemed advisable such money may be applied in such other way as the trustees for the time being may think fit, provided such money is only used for the purpose of promoting Science." The late Mr. Langworthy deserves credit not only for his liberality, but for the sound and advanced views he held as to how Science should be taught, and as to the necessity of encouraging original research in connection with the chairs of Science in our Universities. Mr. Langworthy has also bequeathed 10,000*l*. each to the Salford Library and Museum, and to the Manchester Grammar School, in the latter case for the purpose of founding twenty scholarships.

THE Chair of Chemistry in the University of Glasgow is vacant. We hope the Home Secretary in filling up the vacancy will, in the spirit which urged the late Mr. Langworthy to make the magnificent bequest above referred to, show by the appointment he makes the appreciation in which he holds original research. It is now high time that it should be distinctly understood that no man deserves to be appointed to a Chair of Science in any of our Universities unless he has shown that he has that knowledge of his subject which can only come from original investigation.

THE Professorial Chair of Physiology in University College, London, has become vacant by the resignation of Dr. Sharpey, who has held it since the year 1836.

SIGNOR L. M. D'ALBERTIS, the distinguished Italian traveller, who has lately penetrated into the mountains of New Guinea, and discovered the remarkable Bird of Paradise which bears his name (*Drepanornis albertisi*), has just returned to this country from Sydney, *viâ* San Francisco, bringing with him his large collection in every department of natural history which he formed during his expedition.

WE would call attention to the Swiney Course of Lectures on Geology which are at present being delivered by Dr. W. B. Carpenter, F.R.S., in the Middle Class School, Cowper Street, Finsbury. The course was commenced last Thursday, and will be continued on Mondays and Thursdays at 8 P.M.; there will be twelve lectures in all. We are sure that many of our London readers, on being made aware that such a course of lectures is being delivered by such an authority, will be glad to take advantage of the opportunity, especially as the lectures are free to the public.

THE first of the course of lectures at the Zoological Gardens given in pursuance of the provisions of the Davis Trust, was delivered on Tuesday the 14th, by Mr. P. L. Sclater, being an Introductory Lecture on the animals in the Gardens, of which he gave many particulars that seemed greatly to interest the audience. Last Friday Mr. Sclater gave the first of his course of four lectures On the Geographical Distribution of Mammals, in which he dealt with the general laws of the distribution of animals on the globe. Both lectures were well attended, the picture gallery being nearly full.

At the annual election to Mathematical and Physical Science Postmasterships in Merton College, Oxford, early in October an election will be made to two Physical Science Postmasterships, each of the value of 80*l.* a year, and tenable for five years from election, provided that the person elected do not accept any appointment interfering with the full course of academical studies. There is no limit of age, but candidates, if already members of the University, must not have exceeded six Terms from Matriculation. The persons elected, if not members of the University, will be required to pass the University Examination for Responsions within a year of election. The subjects of examination will be Chemistry and Physics. There will be a practical examination in Chemistry. Candidates will have opportunities of giving evidence of a knowledge of Biology; but it must be borne in mind that in such cases the examiners will look for evidence of an acquaintance with the principles of Chemistry and Physics equal in extent to that which is required in the Preliminary Honour Examination in the Physical Science School. A paper will be set in algebra and elementary geometry, which, *cæteris paribus*, will be of weight in the election to Postmasterships. Further information may be obtained from the Tutor in Physical Science.

Mr. R. Hind, writing to the *Times*, sends the positions of two telescopic comets, discovered within the last ten days. He says:—"The first was detected by Prof. Winnecke, at Strasburg, on the morning of April 12. It is a diffused nebulosity, about four minutes in diameter, somewhat extended on the side opposite the sun. Our observations during the past night give the following place:—April 21, at 3h. 22m. 9s. A.M., mean time at Twickenham—right ascension, 20h. 50m. 41·6s.; polar distance, 88° 10′ 50″; present diurnal motion about 5′ in R.A., and 1° 5′ in P.D., both decreasing. The second comet was found by M. Coggia at Marseilles, on April 17. It is much smaller than the above, but has a strong nuclear condensation. Last evening its observed position was:—April 20, at 9h. 47m. 15s. mean time—right ascension, 6h. 25m. 15·6s.; polar distance, 20° 15′ 23″. Its motion is slow, towards the south-west.

The instruments used by Dr. Livingstone in his last journey, a sextant, thermometer, and chronometer, are still exhibited in the map room of the Royal Geographical Society, together with some of his maps made in 1856-7. Those who have not before seen any of the maps will be interested in noticing the great care and neatness with which the work is done, and the amount of information crowded into them. There are also several portraits of the traveller taken at different periods.

At the last meeting of the Linnean Society, Dr. Masters and Messrs. Hiern and Maw were appointed to represent the Society at the forthcoming congress of botanists in Florence.

The removal of the Library of the Geological Society from Somerset House to Burlington House, has been completed.

Mr. Leonard Lyell, B.Sc., has been appointed Professor of Natural Science in the University College of Wales.

The Brothers Henry, astronomers at the Paris Observatory, have invented a modification of Leon Foucault's process for testing his telescopic glass mirrors. They are using that process at Secretan's in the construction of lenses used for dioptric astronomical instruments. One instrument constructed by them has been tried at the observatory and proved highly satisfactory; an object of an inch is equal to one of two inches when the surface has been worked under their optical supervision. They reject every part of glass which is not perfect. The first *lunette astronomique* so constructed has been sold.

In the last sitting of the Academy, M. Becquerel, senior, one of the greatest electricians of the age, was presented with a medal in commemoration of the Fiftieth Anniversary of the Academy, of which he became a member four years afterwards. In 1824 the sittings were private, and only open to a very few learned persons. The admission was considered to confer a great honour, and was a step preliminary to membership. It was only in 1834 that the secrecy was removed on the proposition of Arago; Biot raised an opposition to it, but was outvoted. The publicity of sittings was coupled with the publication of *Comptes Rendus*, a weekly journal, exclusively devoted to the papers read before the Academy, and which has rendered immense services for a period of thirty-nine years.

We very much regret that Sir John Lubbock's bill for the Preservation of Ancient Monuments was thrown out of Parliament last week by a very considerable majority. Patriotism seems to be at a discount in the House of Commons.

Prof. Bastian, of Berlin, has received favourable news from the German expedition on the west coast of Africa. Dr. Gussfeldt, who is at the head of the expedition, has advanced into the Interior, and reached the Fangela country, which, it is believed, is the right point for further advance into Central Africa. The travellers at the latest dates were at the station of Chinchato, and were busy with the preparations for the more important expedition.

The German exploring expedition into the Libyan Desert, under the leadership of Gerhard Rohlfs, returned to Cairo on April 17.

MM. Andre and Rayet are at present publishing, at Gauthier Villars', a work on "The History of Astronomical Observatories." The first part which is on sale is devoted to British observatories. The learned astronomers remind their countrymen that at the end of the last century France had a greater number of astronomical establishments than all other countries. The same thing can now be said of Great Britain.

Mr. Harrison, as President of the Institution of Civil Engineers, will give a *conversazione* on Tuesday, May 19, in the west galleries of the International Exhibition at Kensington, which have been kindly placed at his disposal by H.M.'s Commissioners. As in the two preceding years, models of engineering works and of recent scientific inventions will be transferred to the west picture galleries from other portions of the Exhibition, and these will be supplemented by similar objects specially lent for the occasion.

Dr. Carpenter has replied to Mr. Carter's letter to Prof. King on the structure of the so-called *Eozoon canadense*. He complains that Mr. Carter makes his charges without having, according to his own admission, read what has been written in favour of the view of the organic origin. In support of this view the examination of specimens by Prof. Schultze at the end of last year is referred to, by which he was completely satisfied as to the Forameniferal character of Eozoon. Dr. Carpenter says he does not pretend to affirm that the doctrine of the Forameniferal nature of Eozoon can be *proved* in the demonstrative sense; but he does affirm that the convergence of a number of separate and independent probabilities all accordant with that hypothesis, while a separate explanation must be invented for them on any other hypothesis, gives it that *high probability* on which we rest in the ordinary affairs of life, in the verdicts of juries, and in the interpretation of geological phenomena generally.

The Society for Promoting Christian Knowledge has begun to issue a series of "Manuals of Elementary Science." Is it to be regarded as a sign of the times that this Society as a publishing body is devoting to the spread of a knowledge of Science funds which have been avowedly collected for the purpose of "promoting Christian knowledge"?

The re-mapping of England by the Geological Survey, giving the drift in its various divisions is steadily progressing, and in a short time a large part of Lancashire will be published. The quarter sheets, numbered by the survey 81 N.W., 88 S.W., 89 S.E., 90 S.E., 91 S.W. are engraved and in the hands of the colourist, and the work for 91 S.E., 90 N.E., 89 N.W. has been completed and the maps are in the engravers' hands. The sheet N.E. Somerset, and the London district have been ready some time. The old maps giving the rock mapping will continue on sale, for information that cannot be so readily gained in any other way arises from a comparison of the mapping of the rock with that of the surface drift.

According to the Abbé David, the Chinese river Hangkiang, until lately almost unknown, is an important river of commerce, traversed by vessels of every size. A considerable portion, however, is difficult of navigation, owing to the existence of numerous rapids and many rocks.

The death of Rev. John Bachman is announced as having taken place at Charleston on February 24. In the decease of this gentleman, Science loses one of the oldest of American naturalists, and one who has been quite prominent in the history of American zoology. He is well known from his association with Mr. Audubon in the preparation of the great work on the North American mammals, of which one edition was published, in folio, at 400 dols., and another, in quarto, at 40 dols. This, as far as its illustrations and biographies are concerned, still forms the standard treatise on the subject, although the systematic portion has been in a measure superseded by later and more critical investigations. It was, however, preceded by several monographic papers upon squirrels, hares, shrews, and other species, and also by papers upon the seasonal and other changes in colour in birds and mammals. Dr. Bachman's friends claimed for him the distinction of having been the first person in the United States to practise the art of artificial impregnation of fish, although this is stoutly contested by Dr. Garlick and other writers.

Mr. R. B. Walker writes from Corisco Bay, in Western Africa, in regard to a young gorilla which he had alive for some time, and hoped to forward to the Zoological Society of London. Contrary to the usual assumption in regard to this species, the specimen in question proved to be extremely docile and perfectly tame. When first purchased it was shy and suspicious, but not spiteful. At the expiration of about a week it was led around without resistance, and it ate whatever eatable thing it could lay its hands on, including a basin of condensed milk with a raw egg beaten up in it. It was quite tame, eating, sleeping, and playing with a large bull-terrier, the two animals being constantly together. It unfortunately disappeared one night, and was supposed to have fallen overboard.

The forthcoming number of Petermann's *Mittheilungen* will contain the conclusion of the account of the return journey of Count Wiltschek's Arctic expedition through North-east Russia, and some remarks on the geognostic survey map of the coast of the Waigatt Strait in North Greenland, between Disco Island and the mainland, by M. Steenstrup. The number will also contain an account of Gosse and Warburton's travels through West Australia (recently referred to in Nature), accompanied, of course, by an excellent map.

A Roman Company, we learn from *La Nature*, proposes to lay a railway between Naples and Mount Vesuvius.

We would direct the attention of our physiological readers to a short paper which has just appeared in the "Proceedings of the Royal Society," by Mr. E. A. Schäfer, on the Intracellular Development of Blood-Corpuscles in Mammalia, in which he shows, in the subcutaneous tissue of the new-born rat, how the red corpuscles, statically developed together with the primitive capillaries, become the dynamically circulating blood-discs of the older animal, as in the *area vasculosa* of the embryo chick.

We are glad to see that the Leeds Naturalists' Field Club and Scientific Association has just concluded the most successful year of its existence, its operations during the past twelve months having been attended by most gratifying and steady progress. We have received the syllabus of a number of lectures (by Mr. L. C. Miall) and excursions to take place during the present and next months, illustrative of the geology of the West Riding. There will be four lectures, illustrated by seven excursions.

We have received a short and carefully compiled sketch of the Geology of the County of Suffolk, written by Mr. J. E. Taylor, of the Ipswich Museum, a gentleman who, by the popularity of his lectures and the large audiences which he draws, is doing more than anyone to develop a genuine and lasting love for natural history in that part of the country.

Messrs. Longmans & Co. have in the press a "Manual of Industrial Chemistry." It is a translation of Profs. Stohmann and Engler's German edition of Payen's "Précis de Chimie Industrielle," by Dr. J. D. Barry. It will be edited and supplemented with chapters on the chemistry of the metals, by Dr. B. H. Paul, and will be copiously illustrated. The same publishers also have nearly ready an "Introduction to Experimental Physics, Theoretical and Practical," by Adolf F. Weinhold, Professor in the Royal Technical School at Chemnitz, translated and edited by Benjamin Loewy, F.R.A.S.; it will also have a preface by Prof. G. C. Foster, F.R.S., and be illustrated with numerous woodcuts.

The additions to the Zoological Society's Gardens during the past week include a Mourning Kangaroo (*Halmaturus luctuosus*) from the south of New Guinea, deposited by Signor L. M. D'Albertis; two Gold Pheasants (*Thaumalea picta*) from China, presented by the Rev. A. B. Frazer; a White-cheeked Flying Squirrel (*Pteromys leucogenys*) from Japan, presented by Mr. A. Gower, H.B.M. Consul at Kobe; a Common Fox (*Canis vulpes*) from Russia, presented by Mr. J. W. Ouchterlony; a Long-nosed Crocodile (*Crocodilus cataphractus*) from West Africa, presented by Mr. H. T. Cooper; and a Red Kangaroo (*Macropus rufus*), born in the Gardens.

SCIENTIFIC SERIALS

The *Geographical Magazine*, No. 1, April.—Such is the title of the successor to *Ocean Highways*, which a "Notice" informs us, "has been discontinued," Mr. C. R. Markham, C.B., F.R.S., "having taken the editorship of the *Geographical Magazine*, issued under new proprietorship." We certainly prefer the outside appearance of the new magazine to that of its predecessor, the cover being much more tasteful and business-like; it has made an excellent start also as to contents. The first article, accompanied by a map, is on "The Basin of the Helmund," which includes all the streams that flow down into the great lake or swamp of Sistan, and lies athwart the line of advance from the north towards India. A large part of this area is still entirely unknown, and the article gives an account of the existing materials whence a knowledge of the region can be obtained. The next article gives an interesting account of the Russian Staff-Captain N. M. Prshevalski's Travels in Mongolia in 1870–73. Captain Prshevalski "has acquired most valuable scientific information which, combined with the map he intends shortly to publish, will shed a flood of light on the geography, zoology, and botany of Mongolia and Northern Thibet." This is succeeded by an article on "The Hydrographical Department of the Admiralty," giving a brief history of this most important department of the naval service, and a sketch of its labours. The article contains some valuable hints as to how the department might be made more efficient than it is if Government would only be a little more wisely liberal. An article on the Island of Hormuz, by Lieut. A. W. Stiffe, gives an account of the present state of the island and of the remains of its ancient grandeur. We can only name the other original

articles :—"A Highway to Bolivia," by Mr. Alfred A. Geary ; "The Kashgar Mission," of Mr. Forsyth and party ; "Dr. Beccari's Travels," in which Prof. H. H. Giglioli gives the latest news of the Italian traveller and naturalist, who has left Makassar for Kandari, an unexplored region of S.E. Celebes, where he hopes to secure specimens of the great Anoan antelope (*Anoa depressicornis*) ; "Geographical Progress in India in 1873 ;" and "the Products of West Africa," by M. W. Robinson. There are, besides the usual Reviews, Correspondence, Proceedings of Societies, &c.

Bulletin de l'Académie Royale de Belgique, No. 2, 1874.—The principal paper in this number is one by M. Montigny, in which it is sought to show that "the frequency of variations of the colours of stars in scintillation is generally in relation with the constitution of their light, according to spectral analysis." The author's observations embrace two distinct periods—one from Oct. 1870 to end of March 1871 (47 nights of observation), and the other from June to Dec. 1873 (19 nights). After referring to Secchi's three types of star-spectra, he gives a table of the stars observed, indicating the type of spectrum, the scintillations observed in a second at 60° zenith distance, the size, &c. It is found (1) that the stars scintillating most belong to the first type, or those with four spectral lines, while the stars showing weak scintillation are generally in the third group or type of nebulous bands and dark lines ; (2) that the average, 86 (scintillations per second), of the first type exceeds considerably that of the third, which is 56. The average of the second group (the spectra resembling that of the sun) is 69, and thus intermediate, though a little nearer that of the third ; (3) while some stars little differing in size resemble each other also in numerical intensities of scintillation (especially in the first type), no marked connection appears between the frequency of scintillation and the order of size of the stars ; the last two types even present equal mean sizes, though their scintillations differ considerably. The average scintillations of the three types are in proportion of the numbers 14, 11, and 9. The author points out how his researches not only confirm M. Dufour's law that the red stars scintillate less than the white ones, but affords an explanation of it. The more frequent scintillation of the white stars is due to the fact, that, with equal distance of the observer, the total separation of the coloured bundles of rays, dispersed by the atmosphere, and which have emanated from a white star, is greater than in the case of a red star; the original rays of the white star being more numerous and more exposed to undergo frequent interception by the passage of aerial waves.—M. d'Omalius d'Halloy contributes a note on the Devonian system, and MM. Quetelet and Terby give accounts of auroræ boreales observed in January and February.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, March 1.—This number opens with the concluding part of a paper by M. Mühry in orographic meteorology. The author adduces evidence from hygrometric phenomena, that the permanent equatorial ascending-current forms the transition of the polar, into the returning anti-polar, current ; he also proposes a new classification of clouds, according to ascent or descent. Some particulars are furnished, in a note, as to the climate in southern parts of Europe—Gibraltar, Tarifa, and San Francisco : and M. Jelinek translates a paper by Mr. Kingston of Canada, treating of the most suitable arrangement of thermometers in determining the temperature of the air.

March 15.—The beneficial effect of Alpine health-resorts has been attributed to the greater abundance of ozone in the mountain air. Dr. Haller here communicated the result of observations on the subject in July 1872 and 1873, made at Fusch Bad, in the Alps, at a height of 1,179 metres. Comparing data obtained at the meteorological central observatory of Vienna (194 metres), it appears, that in the bright and warm July of 1873, the ozone-contents of the air at Fusch Bad were considerably greater ; by night about 2°·3, and by day 2°·6. In July of 1872, which was cold and rainy, the average of ozone was by night somewhat less (0·6) at Fusch Bad than at Vienna ; by day, however, it was 2° greater. It seemed likely that, on further ascent, an increase of ozone would be met with, but after climbing to 23,000 metres, there was no marked difference.—This paper is followed by an account of M Poey's recent observations (French Academy), on the relation between sun-spots and cyclones in the Antilles.—From a study of meteorological phenomena at St. Louis, Dr. Wislizenus finds that the electricity of the atmosphere shows a three-fold periodicity, daily, yearly, and secular (or cyclical). As to the second, the quantity of positive electricity increases in the colder months, reaches its maximum in January, and diminishes with increase of temperature to a minimum in July. The cyclical periodicity is probably one of ten years.—Among other subjects treated in this number are the formation of rain-stations in Bohemia, the inadequacy of the ozonometer at present in use, the decrease of water in springs, rivers, and streams.

Gazetta Chimica Italiana. Fasc. I. e II. 1874. These numbers contain the following papers :—Studies in Toxological Chemistry. I. Search for solanine in cases of poisoning. II. Extraction of the alkaloids from the viscera, and search for nicotine, brucine, and strychnine. III. Detection of hydrocyanic acid in cases of poisoning, by Prof. F. Selmi.—Old and new Reactions of ordinary Phenol, by E. Pollaci.—A product of condensation of Oxalic Aldehyde, by H. Schiff. The substance obtained is formed according to the equation $6C_2H_2O_2 + H_2O = C_{12}H_{14}O_{13}$.—Action of Amides upon the Phenols, by Dr. J. Guareschi. The author has tried the following reactions :—paracresol and benzamide, methyl salicylate and benzamide, and ethyl salicylate and benzamide.—Concerning the action of Sulphur upon Calcium Carbonate, by Prof. A. Cossa.—Reduction of Silver Chloride by means of Sodium Hydrosulphite, by G. Scurati Manzoni. The chloride is reduced according to the equation $Na_2SO_2 + 2AgCl = 2Ag + 2NaCl + SO_2$.—On the Expansion of Fused Sulphur, by G. Pisati.—Upon the Reactions of Phenol, by G. Tasca-Lanza. The remainder of these numbers is principally devoted to abstracts from foreign journals. There is also a complete translation of Prof. Clerk-Maxwell's lecture on molecules, which has already appeared in our columns.

Journal de Physique, March.—This number commences with a paper by M. Bertrand, in which several known theorems relating to static electricity are demonstrated in a new and simple manner, which reduces them to a common principle.—M. Chautard describes an improvement on Mayer's acoustic pyrometer.—M. Lespiault calls attention to a new method proposed by M. Galle for estimating the height of the corona of aurora borealis. As applied to the aurora of February 1872, it gave 56 geographical miles (or 415 kilometres) for the absolute height. The agreement between results obtained from four different stations appears to confirm the principle on which M. Galle's method is based.—An ingenious mode of sending signals in opposite directions simultaneously, in a telegraphic apparatus of compressed air, is described by M. Deprez.—M. Gripon gives an account of some experiments made with a tuning-fork ; referring to movement of cords or wires connected with it, vibration of wires in liquids, movement of liquid in a tube vibrated by fork, &c.—We further note a useful summary, by M. Violle, of MM. Favre and Valson's recent researches in crystalline dissociation, and an account of Prof. Tyndall's investigation as to acoustic transparency and opacity of the atmosphere.

Reale Istituto Lombardo di Scienze e Lettere. Rendiconti : t. vii. Fasc. iv.—In this number we find the continuation of Prof. Lombroso's researches on anthropometry and physiognomy of criminals. The results arrived at, from an extensive range of observation, are worthy of study. Among other things, the author concludes that criminals have, in general, a greater stature and weight, more ample chest, and darker hair than the normal ; that they present a series of sub-microcephali (53 to 51) double the normal ; that the index of the cranium tends to the brachicephalic, especially in assassins ; that there is frequent cranial asymmetry ; that, tested by the dynamometer, criminals show less force than the normal, but greater than lunatics ; that, more often than in sane people, the eyes are chestnut or dark, and the hair is thick and black (especially in murderers) ; that incendiaries, and, still more, thieves, have very often the iris grey, and always a stature, weight, muscular force, and cranial capacity less than assassins or homicides. In concluding his paper, Prof. Lombroso remarks that prognathism, abundance and curliness of hair, scarcity of beard, frequent dark colour of skin, oxycephalus, obliquity of the eyes, smallness of cranium, development of jaws, retiring forehead, large size of ear, similarity of the two sexes, and scant muscular force, are points of resemblance between the European criminal and the Austral or Mongolian man.—Dr. Polli traces the recent progress of the doctrine of zymotic disease, and of the treatment of it with sulphurised preparations. Figures are given which show the largely increased production of sulphite of magnesia and sulphite of soda by certain chemical works in Italy, for medicinal purposes alone, within the last ten years.—MM. Bizzozero and Manfredi contribute a note in patho-

logical anatomy, On the Development of Contagious Molluscum.—The Architecture of Ants forms the subject of a communication from Prof. Maggi, who has been studying the habits of *Formica fuliginosa* Lat.—M. Tessori furnishes a geometrical demonstration of the error of representations given in many treatises on physics, as to deviation of the plane of oscillation of the pendulum.—In the department of moral and political science, Prof. Bucellati has a paper on central military prisons.

Archives des Sciences Physiques et Naturelles, March 15.—This number commences with a *resumé* of spectroscopic observations of the sun, made at Geneva, by M. Emile Gautier during the last three years. The results of this work (carried on under much less favourable climatic conditions than in Italy), are mainly a confirmation of those got by other observers. The protuberantial phenomena are classed under three heads; eruptions, exhalations, and detached formations; all of which the author illustrates with drawings. Like P. Secchi he was often struck by the fact (which has been doubted), that when a protuberance is observed near a pole, there is generally one symmetrical with it, at the other end of the corresponding solar diameter, and near the opposite pole. The decrease in the number and dimensions of protuberances appeared during these years (from 1869) to precede and exceed that of the spots. M. Gautier adheres to the hypothesis of spots being formed by scorial matters resulting from cooling of the surface by radiation.—In the next paper M. Humbert gives a useful summary of what has hitherto been done by the *Challenger* expedition.—The *Bulletin Scientifique*, which follows, is larger than usual. Among other notes in it, we find an account of some instructive researches by Dr. Macaluso, on polarisation of electrodes, by chlorine and hydrogen. There is also a notice of an important geological map of the Austro-Hungarian Empire, recently completed by M. de Hauer, whose name it bears. The publication, directed by Heidenhain from 1850 till 1863, represents at least twenty years' labour (under considerable difficulties), of a large number of eminent geologists. Each plate is accompanied with detailed explanations. We further note a *résumé* of some recent researches on the minute structure of the eye; and another paper on physiological antagonism of poisons, in which are described some observations by MM. Martin-Damourette, Rossbach and Fröblich, and others, with regard to the effects of physostigmine, the active principle of Calabar bean, and atropine.

SOCIETIES AND ACADEMIES

LONDON

Mathematical Society, April 9.—Prof. Cayley, vice-president, in the chair.—Mr. G. H. Darwin read a paper On Probable Error in Statistics. He stated that he had been at work at a statistical inquiry, and was desirous of forming some idea of what degree of accuracy he had a right to expect from the collection of a given number of cases. He put the problem into the following form:—A bag is known to contain a very large number of black balls and white balls, mixed at hazard; on drawing a large handfull of n balls, I find p are white and the rest black. What is the probable error in asserting that $\frac{p}{n}$ of all the balls in the bag, are white? n and p, though large numbers, are supposed to be small compared to the number of balls in the bag. Mr. Darwin then made some further remarks On the Combination of Statistics. The question he considered was the following:—If X and Y are measurements or estimations of quantities such that the errors are distributed according to the exponential law, what is the "probable error" of XY and $\frac{X}{Y}$ in terms of the moduli c and c' of X and Y respectively? M. J. W. L. Glaisher made some remarks on the papers, drawing the author's attention to the fact that the two questions had been treated of by Laplace and De Morgan.—Mr. Merrifield then gave a sketch of his paper entitled Determination of the Form of the Dome of Uniform Stress. He remarked that the general question of the equilibrium-figure of a thin dome is indeterminate, even when the law of thickness or density is given, and it thus differs from the question of the arch, by requiring the assumption of a further condition in order to render its form determinable. If the two following conditions are introduced simultaneously into the general equations, he stated that a very remarkable simplification occurs in the analysis:—(1) that the thrust along a meridian hall equal the thrust along the parallel per unit of area at every point; (2) that the normal thickness shall vary in such a manner that the area under compression shall be proportional to the thrust. These seem to be the conditions necessary to the economical use of building materials of homogeneous character, for the maximum stretch is evidently least when the stress is equally distributed through the whole of the material. The form obtained bears a general resemblance to the upper half of a claret bottle, and the dome evidently required a heavy lantern.—Mr. A. J. Ellis gave an explanation of his theory that ordinary (commutative) algebra is the calculus of similar triangles upon one plane. Taking two fixed points O and I, any third point A determines a triangle, so that if B be a fourth point, it is immediately possible to find a fifth point C, such that the triangle BOC shall be similar to the triangle IOA, and have the angles thus named turned in the same direction. Marking this operation by a, as being determined by the position of the point A, and terming it a *clinant*, he showed that clinants obey every law of commutative algebra, so that it was possible to consider any and every existing algebraical expression as a clinant, and hence as determining a point in a plane. Clinants thus embraced not only the integers and fractions of ordinary arithmetical algebra, but incommensurables, negatives, and imaginaries. Hence also if x and y be any clinants, and $f(xy) = o$, if x be determined by taking X anywhere, a corresponding point Y would be determined. Hence arose a complete calculus of the correspondence of points in a plane, which Mr. Ellis calls *stigmatic geometry*, and which he showed comprehended under one set of equations and greatly generalised, not only the algebraical geometries of Descartes and Plücker, but the homographic geometry of Chasles, and from a single general principle gave a perfect geometrical representation of all the imaginary cases as part of one conception with the real cases. The actual algebraical work, though having the old form and obeying the old laws of operation, is greatly simplified by the clinant signification attached to the symbols, and in especial the expression and determination of direction is rendered easy and certain. (A more detailed explanation will be given, the speaker said, in his "Algebra Identified with Geometry," at the present time in the printer's hands.)—Prof. H. J. S. Smith made a short further communication in reference to his former paper On the Higher Singularities of Plane Curves.—A paper by Mr. H. M. Taylor, On Inversion, with special Reference to the Inversion of an Anchor-ring, was taken as read. Some of the properties given in the paper have been already given by Maxwell (Quart. Journ. Math., vol. ix.) where excellent stereoscopic views of four species of cyclides are given, and by Cayley in the same journal, vol. xii., and in a paper in the Phil. Trans. by Casey. The novelty of the paper consisted in the point of view from which the properties of the cyclides are investigated, viz. as the inverse figures of the anchor-ring, many of whose geometrical properties are as easily seen as those of the circle.

Linnean Society, April 16.—H. Trimen, M.B., in the chair.—A number of papers were read, being Nos. 3-14 of the series of contributions to the botany of H.M.S. *Challenger* Expedition, as follows:—Notes on Freshwater Algæ collected in the boiling springs at Furnas, St. Michael's, Azores, and their neighbourhood, by H. N. Moseley.—Note on the foregoing communication, by Prof. Thiselton Dyer.—Notes on some collections made at Furnas, by M. Archer. The diatoms belong to species of most frequent occurrence in fresh water, and appear to be in no way affected by the high temperature. The other Algæ are mostly common species, several of them British, belonging to the genera *Spirogyra*, *Mesocarpus*, *Bulbochæte*, *Œdogonium*, &c.—Notes on plants collected at St. Vincent, Cape de Verdes, by H. N. Moseley—Enumeration of Algæ collected by Mr. Moseley at the Cape de Verdes, by Dr. G. Dickie.—Enumeration of the fungi collected during the expedition of H.M.S. *Challenger*, Feb.-May 1873, by the Rev. M. J. Berkeley.—Note on plants collected at St. Paul's Rock, by H. N. Moseley. The only aërial plant found on the island was a *Chlorococcus*.—Enumeration of the Algæ collected by Mr. Moseley at St. Paul's Rock, by Dr. G. Dickie.—Notes on plants collected at Fernando Noronha, Cape de Verdes, by H. N. Moseley.—Enumeration of Algæ collected by Mr. Moseley at Fernando Noronha, by Dr. G. Dickie.—Enumeration of Algæ collected by Mr. Moseley in 30 fathoms of water at Barra Granda, Pernambuco, by Dr. G. Dickie.—Enumeration of Algæ collected by Mr. Moseley at Bahia, by Dr. G. Dickie.

Chemical Society, April 16.—Prof. Odling, F.R.S., presi-

dent, in the chair.—Dr. A. W. Tilden read a paper On Aqua Regla and the Nitrosyl Chlorides. He finds that when the gases evolved on gently heating aqua regia are passed into concentrated sulphuric acid, a product is obtained which, at a low temperature, deposits crystals of nitrosyl sulphate, $NOHSO_4$. Both these crystals, and the liquid producing them, when mixed with sodium chloride and gently heated, evolve nitrosyl chloride NOCl, an orange-yellow gas which may be condensed to a deep orange-red liquid boiling at -8° C. The author could not obtain the dichloride $NOCl_2$, which Guy Lussac supposed to exist, but which he believes to be merely a solution of chlorine in the monochloride.—Dr. C. R. A. Wright then read a paper On Isomeric Terpenes and their Derivatives, Part IV. § 1. On Cajeput Oil, by C. R. A. Wright and C. Lambert. It was found that the cajeputol, $C_{10}H_{18}O$, boiling at 176°—179° C., obtained from oil of cajeput, combines with bromine forming the compound $C_{10}H_{18}Br_2O$. On heating this it splits up into cymene, $C_{10}H_{14}$, hydrobromic acid, and water. § 2. Action of Pentasulphide of Phosphorus on Terpenes and their Derivatives, by C. R. A. Wright. When cajeputol is treated with the pentasulphide, it yields a mixture of terpene and cymene, the latter being formed by a secondary action of the pentasulphide on the terpene. This was shown really to be the case by treating the terpene from oil of turpentine and hesperedene with the pentasulphide, when cymene was formed in both cases.

Anthropological Institute, April 14.—Prof. Busk, F.R.S., president, in the chair.—Mr. John Brent exhibited and described a series of flint implements from Canterbury and Reculver.—A description, by Mr. Howorth, was read of an Ashanti fetish letter, or curse. The document, which was lent by Capt. Gordon for exhibition, was written in the Arabic character and in the language of the Barbu tribe, on a sheet of rough paper of large foolscap size, folded about two inches square and tied with green thread. The letter contained a prayer that the English might fight among themselves and return to the coast, and that pestilence might overtake them. The Ashanti grievances were enumerated, and it stated that the white man came with covetous eyes and seized the land, and that covetousness brought down the curses of Suleiman the high priest. It was thought by the English scouts that it was Suleiman himself who endeavoured to stay the British troops on their approach by throwing down the fetish, and that his failure would probably cost him his life.—Capt. S. P. Oliver, R.A., contributed a series of papers On the Non-historic Stone Relics of the Mediterranean. The series comprised full accounts, with ample illustrations, of the Torre dei Giganti, Malta; Tumuli near Smyrna; Dolmen-mounds of the Albegna; Sardinian Nuraggls; and the Sepolture de is Gigantes of Sardinia.

Meteorological Society, April 15.—Dr. R. J. Mann, president, in the chair.—On the Climate of Patras, Greece, by Rev. H. A. Boys. The author shows that the climate of Patras is naturally mild and relaxing, seldom disagreeably dry, and not often very damp, being indeed drier by a good deal than any part of England.—Remarks on the Atlantic Hurricane of August 20 to 24, 1873, by W. R. Birt.—On the Meteorology of December in the southernmost part of the Southern Indian Ocean, by Robert H. Scott, F.R.S. This paper has been prepared for the purpose of giving information on the climate of Kerguelen Island to those gentlemen who are going out to observe the Transit of Venus in December next.—On the Diurnal Variations of the Barometer, by J. K. Laughton. Whilst it has long been well known that barometric maxima and minima occur daily with unfailing regularity, especially within the tropics, the cause of this recurrence is yet unknown; and though it has been attributed to the different temperature and humidity at different times of the day, such explanation is far from satisfactory, for the maxima occur at the times of mean temperature and humidity without regard to the direction of the change, and the minima occur indifferently at the times of both greatest and least temperature and humidity. It seems that an explanation is rather to be found in the inertia of the atmosphere, which in the first instance permits its elastic force to be increased by a rapidly increasing temperature before the inertia of rest can be overcome sufficiently to allow it to enlarge its volume in due proportion, but when that inertia of rest is overcome, then the inertia of motion permits it to move away from the place of observation in excess of what is due to the increased elasticity; the nocturnal maximum and minimum being caused by the resilient power of the air, which gives it alternately an inward and outward motion, and each way in excess of what is due to the decrease or increase of elasticity by reason of the inertia of motion. If this explanation is correct, we ought to find a certain tendency of the wind towards east in the morning and towards west in the evening; and this tendency does seem to be shown in the very few published observations which permit a comparison to be made. Further observations, as confirming or disproving the proposed theory, are much to be desired.

Victoria Philosophical Institute, April 13.—Mr. Edmund W. Gosse, of the British Museum, read a paper On the Ethical Condition of the Early Scandinavian Peoples, in which he illustrated the peculiar features of the civilisation of Scandinavia in pagan times, and showed in what salient points that civilisation differed from the spontaneous developments of morality in other cultivated heathen races—the Elder or Poetic Edda of Sœmund Sigfussen being taken as the text.

MANCHESTER

Literary and Philosophical Society, March 24.—Rev. William Gaskell, vice-president, in the chair.—On some of the Perplexities which the Art and Architecture of the Present are preparing for the Historians and Antiquarians of the Future, by the Rev. Brooke Herford.—A Few Observations on Coal, by E. W. Binney, V.P., F.R.S. From his observations the author was led to conclude that soft or cherry coal was chiefly composed of the bark, cellular tissue, and vascular cylinders of coal plants with some macrospores and microspores. That caking coal had much the same composition, except that it contained a greater proportion of bark in it. That splint coal had a nearly similar composition, but with a great excess of macrospores. That cannel coal, especially that yielding a brown streak, was formed of the remains of different portions of plants with a great excess of microspores, which had long been macerated in water. These conclusions were arrived at merely as to the composition of the different kinds of coal. No doubt each seam would be materially affected by the nature of the roof, whether the latter was an open sandstone or a close and air-tight black shale or blue bind, for the former would allow the free escape of gaseous matter, and the latter would prevent its escape. It is well known that the character of the roof has a deal to do with the quality of the coal under it.

April 7.—E. W. Binney, F.R.S., vice-president, in the chair.—The chairman exhibited to the meeting some portion of the cast-iron roof from the Salford Station of the Lancashire and Yorkshire Railway, which after having been up for a period of four years was so much corroded and damaged that it had to be taken down. He attributed the effects to sulphuric acid and soot arising from the combustion of the coal used in the locomotives passing under it, aided by the action of steam and vibration.—On the Action of Nascent Hydrogen or Iron, by William H. Johnson, B.Sc. In a paper read before the Society last year, the author showed that a piece of iron immersed in hydrochloric, sulphuric, or other acid which evolves hydrogen by its action on the metal, on breaking gives off bubbles of gas from the surface of the fracture. It subsequently occurred to the author that these bubbles might be produced by subjecting the metal to the action of nascent hydrogen for some time, and without the aid of acid at all. To test this he connected two pieces of iron wire ·07″ diam. respectively with the copper and zinc plates of a battery of 50 Daniell's cells and immersed them in a vessel of Manchester town's water at a distance of one inch apart. On closing the current, bubbles of hydrogen were given off from the wire connected with the zinc, but none from the wire connected with the copper, the oxygen liberated at the pole apparently forming oxide of iron which in 12 hours formed a thick smudge at the bottom of the vessel. After 24 hours the surface of the wire connected with the zinc was unchanged, but on moistening the fracture bubbles were given off abundantly just as if it had been immersed in acid. The other wire, on the contrary, though much oxidised and eaten away, did not give off bubbles when broken. A variety of experiments were made in the same way with similar results. The author concludes that if the oxidation of the surface of iron be as a rule accompanied by the absorption of nascent hydrogen into the interior of the iron, then the diminution of strength and toughness consequent on this will affect iron ships, telegraph cables, and other structures in which iron is largely used and which are constantly immersed in water.

EDINBURGH

Geological Society, March 13.—Mr. Andrew Taylor exhibited a specimen of coal converted by a recent explosion in

a Lancashire pit into anthracite, and even in some parts into graphite.—A paper by Mr. Payne was read, On the Oolitic coalfield of Brora, Sutherlandshire. One of the coal-seams, about 3 feet 6 inches thick, is being worked at a depth of from 720 to 300 feet.—Mr. Taylor then read three short papers on (1) An analysis of various coals and peats. (2) Specular iron recently discovered in New South Wales. (3) Shale recently discovered at Waitata, New Zealand.—Mr. Peach stated that, in the course of preparing these sections, he had made a discovery which may yet prove to be of some service in the Fine Arts, viz., that the pounded dust of such shale as this, an enormous bed of which occurs in New Zealand, yields a colouring material closely resembling sepia, a costly substance.

April 16.—Mr. David Milne Home, F.G.S., president, in the chair.—The first paper was read by Dr. Ramsay H. Traquair, Keeper of the Natural History collection in the Edinburgh Museum of Science and Art, On the Structure and Affinities of the genus Cheirolepis. Dr. Traquair submitted the following conclusions at which he had arrived on the matter:—(1) That Agassiz was correct in ascribing branchiostegal rays and irregular dentition to the cheirolepis, but the larger teeth are placed in a distinct row internal to the smaller ones, not in the same line as Agassiz described them. (2) That the plates described by Powrie as principal jugulars belong to the shoulder girdle, being in fact the interclavicular plates of Parker; and that cheirolepis has no jugular plates. (3) That the osteology of cheirolepis shows it to be so closely allied to Palæoniscus that it ought to be included in the same family, notwithstanding the minuteness and non-overlapping character of the scales.—Mr. George Lyon read a paper On a Species of Griffithides (Trilobite) from a limestone quarry south of Dalkeith, near Edinburgh, and which belongs to a genus extremely rare.—Mr. David J. Brown read a paper On a new Theory of the Formation of Till, or Boulder-clay. The author submitted that till is in reality formed by glaciers, after they enter the sea, tearing up the rocks that form its bed, and grinding them to boulders and mud, and that this mud deposited along with the boulders forms boulder-clay.

VIENNA

Geological Institute, Jan. 7 (anniversary meeting). The Director, Fr. v. Hauer, read the annual report, which states, that during the last year the palace of Prince Liechtenstein has been purchased for the collections, the library, laboratory, and the working rooms of the institute. The staff has been reorganised, and now consists of the Director, Fr. v. Hauer; Vice-Director, Fr. Foetterle; Chief Geologists, D. Stur, G. Stache, and E. v. Mojsisovics; Chief of the Chemical Laboratory, K. v. Hauer; Geologists, H. Wolf and K. Paul; two adjuncts, O. Lenz, the second at present being vacant; two assistants, A. Redtenbacher and K. John; two practitioners, C. Doelter and R. Hörnes.—After mentioning the share which the institute took in the general exhibition of last year, the report announces that geological explorations have been carried on during the last summer in the Bukovina as well as in the Tyrol, whence the examination of the northern chain of the Austrian Alps was finished with the Bregenzer-Wald (Vorarlberg), whilst that of the central chain was continued in the environs of the Oetz valley and the Ortler mountains, and that of the southern chain was begun in the environs of Lienz, in the valley of the Drau. Grateful allusion is also made to the liberal foundation of a capital of 12,000 florins in bonds of the Southern Railway Company, the gift of Albert Schloenbach, of Salzgitter, Hanover, in memory of his late son, the eminent geologist, Urban Schloenbach. The annual interest of this sum will be given to officers or friends of the Geological Institute, to enable them to travel in foreign countries to compare geological observations made in the Austrian dominions with those abroad. The first to whom it has been granted is D. Stur, whose studies on the exact geological position of the Bohemian coal-beds are likely to lead to very interesting results; results, however, which require a comparative study of other coal basins, and chiefly of the rich collections of fossil plants in the Museum of Dresden, for their secure confirmation.—The following specimens have been newly arranged in the museum of the Institute:—The silurian fauna of Galizia; the Devonian fauna of Moravia; the carboniferous flora of Ostrau-Orlau-Karwin, of Schazlar-Schwadowitz, of Kladno-Schlan, of Swina, of Stradonitz, of Radnitz and its environs, of the Pilsen basin, of the Rossitz basin, the flora and the fauna of the old red in Austria, Moravia, and Bohemia; the cretaceous flora of Moravia and Bohemia; the flora of many tertiary deposits in Bohemia, and of Wieliczka and Swaszawicœ, in Galizia. In the chemical laboratory, more than 300 analyses and assays have been performed, the library has been augmented by 661 volumes, and the collection of maps by 194 sheets. The progress of the publications appears very satisfactory: besides the periodicals, the *Jahrbuch*, the *Mineralogische Mittheilungen* and the *Verhandlungen*, four sheets of the "Memoirs," were edited, viz., Vol. V., No. 4, On a Fossil Saurian from Lesina, with 2 plates, by Prof. A. Kornhuber; No. 5, On the Cephalopods of the Gosau beds of the north-eastern Alps, with 9 plates, by Dr. A. Redlenbacher; No. 6, Fauna of the beds of Aspidoceras acanthicum, with 13 plates, by Prof. M. Neumayr; and Vol. VI., No. 1, The Fauna of the Flambach and Halstatt beds, with 32 plates, by Dr. E. v. Mojsisovich. Also, a Geological Map of the Environs of Vienna, on the scale of 1 : 28800, with explanations by Th. Fuchs, and a Catalogue of the Objects exhibited by the Institute at the General Exhibition, have been published. Finally, the most important work has been the completion of M. v. Hauer's large geological map of the Austro-Hungarian empire, printed in colours on the scale of 1 : 576000, the last four sheets of which were published last year. Further communications were made by T. Hirschwald, On the Transformation of Wood into Brown Coal, in the Mine Dorothee, on the Ober-Starz; by S. Nedeljkovic, On the Sanidin-Trachytes of Syrmia; Dr. A. Redlenbacher, Remains of *Ursus spelæus* from a cavern near Wildalpe, Upper Styria; Dr. G. Stache, On the Fauna of the lower eocene beds of Cosina, in Istria; Dr. C. Doelter, On some Eruptive Rocks in the Transylvanian Erzgebirge.

GÖTTINGEN

Royal Society of Sciences, Jan. 3.—M. Wielen communicated the results of an examination of Greek names of makers inscribed on ancient earthenware lamps in several archæological collections in Athens, Corinth, and Smyrna.—M. Lolling presented a paper on the Theseion and the Hephaisteion in Athens.

RIGA

Society of Naturalists, Nov. 5, 1873.—M. Russwurm furnished some interesting particulars as to the seal-fishing on the Russian coasts. The Baltic supplies annually about 12,000 animals, with a value of 125,000 roubles (the rouble = 3*s.* 1½*d.*); the White Sea and neighbouring parts, 18,000 animals, worth 212,000 R.; the Caspian Sea, 100,000 animals, worth 900,000 R. The Russians (unlike the Finns, &c.) do not eat the flesh of seals, but throw it away. The various species met with, as also the mode of capture, were described.

Nov. 19.—Dr. Gutzeit gave an account of a new official map of Russia, just completed at St. Petersburg.—M. Teich communicated some observations on the power of scent in butterflies; he thinks they are greatly guided by the sense of smell, which has its seat in the feelers.

Dec. 3.—Prof. Petzholdt read a paper on structural relations of ice and axes of crystals.—Prof. v. Sivers made some observations on driftwood collected in the Arctic regions by the recent German expedition.

CONTENTS

THURSDAY, APRIL 30, 1874

THE FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

Association Française pour l'Avancement des Sciences. Comptes Rendus de la 1[re] Session, 1872. Bordeaux. (Paris, 1873.)

THIS, the first volume of the yet young French Society's Proceedings, does it infinite credit. It is a handsome, beautifully printed volume of 1,330 pages, containing upwards of 200 papers, addresses, and lectures on a wide variety of subjects connected with Science, pure or applied. The volume is also well illustrated, some of the plates appended being coloured, a feature which we think the British Association would do well to imitate in its "Proceedings."

The French Association, as our readers no doubt know, made a very auspicious start, the number of members amounting to somewhere about 800. There are two classes of members—1st, *membres fondateurs*, who subscribe one or more shares of the capital of the Association, a share amounting to 500 francs; there are about 250 members of this class, some of whom have subscribed several shares, among the latter being a considerable number of railway and other public companies: 2nd, ordinary members, paying an annual subscription of 20 francs, or a life-subscription of 200 francs; the names of about 50 life-members are in this volume. After an existence of scarcely three months, the Association possessed a capital of nearly 140,000 francs, and an annual revenue of more than 16,000 francs.

The French Association is modelled pretty closely after the older British one, its aim being, according to the rules, "to promote by every means in its power the progress and diffusion of the sciences from the double point of view of the perfection of pure theory and of the development of their practical applications." These ends it proposes to accomplish by means of meetings, lectures, publications, and donations of instruments or money to persons engaged in scientific researches. It appeals for help to all those "who believe that the cultivation of Science is necessary to the greatness and the prosperity of the country."

The Association is divided into four Groups, and each group into several sections; the Groups are—1. The Mathematical Sciences; 2. Physical and Chemical Sciences; 3. Natural Sciences; 4. Economic Sciences. The French Association devotes more attention to the practical application of scientific principles than does the British one; the 1st Group, for example, including Sections of Navigation and of Civil and Military Engineering; the 3rd Group including the Medical Sciences, and the 4th Group Agriculture. This arrangement may at present have some advantages in France, where there are probably fewer special Associations than there are in this country, and because, until the Association gets itself firmly established, it may be advisable to appeal to as many classes of supporters as possible: but we are inclined to believe that it will by and by find that it will serve the cause of Science more effectually by confining its attention to the pure sciences.

In points of administrative detail, the French follows very closely the British Association. One of its rules ordains that each year the capital fund be increased by 20 per cent. of its revenue. If it prospers in the future as it has done hitherto, we have no doubt that it will soon have a very large sum at its disposal.

As we noticed pretty fully the proceedings of the Association at the time of its meeting at Bordeaux in September 1872, it is unnecessary to notice in detail the papers contained in the volume before us. There will be found in its pages the names of many of the most prominent men of Science in France, and a few belonging to foreign countries, among the latter being Sir Benjamin Brodie and Dr. Gladstone. Two of the published lectures have been published in NATURE *in extenso*—that of M. Janssen on the Eclipse of December 12, 1871, and that of M. P. Broca on the Troglodytes of the Vézère.

M. de Quatrefages, the first President, in his eloquent and powerful opening address, speaks very highly, and we would fain hope with justice, of the work which has been done by the British Association. "Thanks to it," he says, "a part of the population has been reformed. The sons of those fox-hunters, who, as a relief from their rude pastimes, only knew of joys equally violent and material, are now botanists, geologists, physicists, and archæologists."

The President's impressive words as to the sphere of Science at the present day are well worth quoting:—"Science is at present everywhere; she is becoming more and more the sovereign of the world. What industry can dispense with the aid of mechanics, and is there any industry which would wish to be bound to the progress already realised by that Science? Is there one which would despise the help of Chemistry? What physician, worthy of the name, would consent to dispense with physiology, that complex science, daughter of chemistry? with physics and with mechanics, any more than with anatomy? What enlightened agriculturist does not understand that the problems of culture and of production are essentially questions of zoology, botany, geology, and chemistry? And in this great city (Bordeaux), one of the queens of universal commerce, what merchant will deny the importance of geography? Science is as indispensable to the military man as to the manufacturer, the physician, the agriculturist. Certainly I am far from denying the part which in war will always fall to courage, to inspiration. But inspiration must be enlightened by study; bravery must be furnished with arms equal to those of the enemy. Revive in imagination Renaud de Montauban or the Roland of legend; place them upon Bayard or Frontin; cover them with their enchanted armour, and dart them against a simple mechanic mounted upon his locomotive. You all know what will be the result of the shock: coursers and paladins will be brayed."

It will be remembered that the first meeting of the French Association took place while the country was yet sore with the humiliation inflicted upon it by Germany; and very naturally the address of the President, as well as the addresses of many others who spoke, took their tone, to some extent, from this condition of affairs. Still the character of these addresses, though intensely patriotic, is perfectly healthy, the various speakers showing

that they possessed a clear perception of the most effectual means of raising and advancing their fallen country; they read aright the lessons of the recent war, and declared that Science alone, in its widest acceptance, could be the saviour and elevator of France. And, indeed, there is the greatest hope of a country that has produced men, and that in so great numbers, capable of doing the work the results of which are chronicled in the handsome volume before us; for we are persuaded that this first volume of the French Association's Proceedings will compare favourably with any single volume of the Proceedings of the British Association. The meeting last year at Lyons fully bore out the promise of the first meeting, and we have no doubt that this year's meeting at Lille will be at least equally successful. Let the members of the Association only do all in their power to keep up its high character and carry out faithfully its declared objects, and the beneficial results of its establishment both to Science and to France will, ere long, be evident. As it is, partly no doubt owing to the work of the Association, Science since the conclusion of the Franco-Prussian war has taken immense strides in France; everything taken into consideration, the amount of scientific activity which has recently been developed in that country is very wonderful, and calculated to call forth the gratitude of the friends of science and humanity.

NORTH AMERICAN BIRDS

A History of North American Birds. By S. F. Baird, T. M. Brewer, and R. Ridgway. Vols. i. ii. and iii. Land Birds. (Little, Brown and Co., 1874.)

THE ornithologists of the United States appear to be not less active than those of this country at the present moment. Whilst here we have Gould's "Birds of Great Britain," Dresser's "Birds of Europe," and Newton's new edition of "Yarrell," all appearing at the same time, so in America Coues's "Key" and Cooper's "Birds of California" are quickly followed by the present important work on the whole of the North American Ornis. For this undertaking Prof. Baird, the well-known Assistant-Secretary of the Smithsonian Institution, has obtained the assistance of two very efficient coadjutors, Dr. T. M. Brewer, of Boston, and Mr. Ridgway, already well known for his accurate work in ornithology.

The object of the present work, which aims at a wider grasp than any of its predecessors, is to give an account of what is known of the birds, not of the United States only, but of the whole of the Continent of North America north of the Mexican boundary. Greenland is included on the one side, and the newly acquired United States territory of Alaska on the other, so that many European and Asiatic forms, which have been lately discovered in these two countries, are now for the first time added to the American list.

The materials upon which this undertaking is principally based consist of the very extensive collections of birds from every part of the New World, in the Smithsonian Museum at Washington. The numerous expeditions for exploration and survey sent out of recent years by the Government of the United States into nearly every portion of their enormous western domain have been invariably accompanied by one or more collectors whose contributions have all been deposited in the stores of the Smithsonian Institution. But besides their collections these investigating naturalists have reaped a rich harvest of facts concerning the life-history of the creatures they have collected, and have deposited their records and journals also in the Smithsonian Archives. From these manuscripts, particularly from the notes of the late Mr. Robert Kennicott, who made most extensive explorations in Western America and in the most northern portion of the Hudsons Bay Territory, many of the most novel facts recorded in the present work have been drawn.

The special value of the researches of Mr. Kennicott and his fellow-workers in the north-west lies in the fact that a large number of the rapacious birds and water-fowl of North America resort in summer to these thinly-populated districts for the purpose of breeding. Their haunts, not having been previously invaded, much novel information on the nesting habits of the members of these two groups is for the first time published in this work.

Besides Messrs. Baird, Ridgway, and Brewer, whose names appear on the title-page, we are informed in the preface that two other well-known American naturalists have contributed to the present work—Prof. Gill having furnished a portion of the introduction, and Dr. Coues the tables of the orders and families.

The work is profusely illustrated by woodcuts, besides containing a series of illustrations of the heads of all the species, drawn upon separate plates. The woodcuts contain the outlines of the principal characters of every genus, embracing the shape of the bill as seen from above and from the side, the comparative lengths of the wing and tail feathers, and the outline of the tarsus and toes; besides reduced but well-executed and highly-characteristic whole figures of many of the species.

The tendency of the American ornithologists of late years has been rather to unduly augment the number of species by raising slight local variations in form and structure to specific rank. In the present work rather the opposite tendency is manifested, and we are not sure that it is not in some instances carried too far. For instance, the whole of the Purple Martins, of the genus *Progne*, recently divided by Prof. Baird into seven or eight species, are now treated of as one; and the different species of Redpole Linnets of Dr. Coues are again reduced to their primitive number. As, however, the distinctive characters, such as they are, are invariably stated with accuracy and precision, it does not really make much difference whether the forms are actually classed as species or varieties.

The three volumes of this elaborate work now before us contain the whole of the Land Birds. A fourth volume, shortly to be issued and to be devoted to the Water Birds, will complete the undertaking. There can be no doubt, as will be at once apparent to anyone who consults the work, that it is of a most complete and exhaustive character, and that it will fully sustain the well-known reputation of Prof. Baird and his fellow-labourers.

OUR BOOK SHELF

Our Common Insects. By A. S. Packard, jun. (Naturalist's Agency, Salem, Mass.)

IN this fully illustrated little work Mr. Packard, the author of the excellent and much larger "Guide to the

Study of Insects," gives a short and popular account of entomology generally, by taking a series of types from amongst the best-known North American insects, and describing them in detail. We should have liked to find some of the descriptions rather more explicit, as they might have been, without any alteration in the size of the volume, if some of the illustrations had not been so frequently repeated. In a work like Euclid there is no doubt considerable advantage in having the figures so placed that it is not necessary to turn over the pages in referring to them, especially when it has to be read by boys; but when space is short and the subject of such general interest, we cannot help feeling that their repetition, three times in more than a single instance, is quite uncalled for. The author's own work at the development of Insecta, which he has published in the "Memoirs of the Peabody Academy of Science," enables him to take a larger view of his subject than that held by most. This is particularly indicated in the very suggestive chapter entitled "Hints on the Ancestry of Insects," in which the researches of Ganin, Lubbock, Brauer, Haeckel, and Müller are all brought to bear on such questions as the relation of the *Zoea* form of the embryonic Crustacean to the similarly undeveloped and generalised, here termed *Leptus*, form of Insecta, in which the configuration is ovate, the head is large, bearing from two to four pairs of mouth-organs resembling legs, and the thorax is merged with the abdomen; this general embryonic form characterising the larvæ of the Arachnida, the Myriapods, and the true Insects. The elaborate observations of the first-named of these authors on the development of *Platygaster error*, an ichneumon parasite, in the author's mind tend to confirm the theory held by him that the ancestry of all the Insects, including the Arachnids and Myriapods, should be traced directly to the worms. We recommend this small book to all interested in the progress of this branch of invertebrate zoology.

The Transactions of the Academy of Science of St. Louis, vol. iii. No. 1. (St. Louis, U.S., 1873.)

THIS volume contains a journal of the proceedings of the Society from March 1868 to January 1873, and a few papers *in extenso*. The latter are:—Notes on the Genus *Yucca*, by G. Englemann; On the new Genus in the Lepidopterous Family Tineidæ, with Remarks on the Fertilisation of the *Yucca*; and Supplementary Notes on *Pronuba yuccasella*, by C. V. Riley; Descriptions of North American *Hymenoptera*, by B. D. Walsh; Atmospheric Electricity, by Dr. A. Wislizenus, being the yearly report of atmospheric electricity, temperature, and humidity, from observations made at St. Louis; Catalogues of Earthquakes for 1871, by R. Hayes; and On the Occurrence of Iron Ores in Missouri, by J. R. Gage. Mr. Hayes, on the basis of the recorded earthquakes from 1739 to 1842 has found that the "largest maxima occurred in the years of the heliocentric conjunction and opposition of Jupiter and Saturn, with but three exceptions, and in these cases the increase began in those years, but the maximum was not reached till the following year." He suggests that "these planets induce electric currents which *call into action* those forces to which the causes of seismic phenomena are usually ascribed."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Herbert Spencer and *à priori* Axioms

MR. HERBERT SPENCER (vol. ix. p. 461) has "ended what he has to say on the vexed question of the origin of physical axioms" by laying down—

(1) That "the perceptions and inferences of the physicist cannot stand without *preconceptions which are the products of simpler experiences than those yielded by consciously-made experiments.*"

(2) That "the preconception which immediately concerns us is the exact quantitative relation between cause and effect."

(3) That "if definite quantitative relations between causes and effects be assumed *à priori*, the Second Law of Motion is an immediate corollary."

By speaking of it as an "*immediate corollary*," I presume that Mr. Spencer means that Newton's Second Law of Motion is the proposition obtained by substituting for the general term, *cause*, the particular term, *force*, and for the general term, *effect*, the particular term, *motion generated*; so that, according to Mr. Spencer, this law simply asserts "a definite quantitative relation between a force and the motion generated by that force." But surely the quantitative relation asserted by Newton is not only *definite*, but is further the *special* relation of *proportionality*; so that, if the law is an immediate corollary of an *à priori* assumption, the assumption must be that "the exact quantitative relation between cause and effect is that of direct proportionality," or in more familiar words, that "effects are proportional to their causes." Perhaps this is what Mr. Spencer meant to assert. At any rate let us admit it as a definite basis for reasoning, and endeavour to deduce some consequences from it.

"The cause of a stone falling when left to itself is its weight; but 'the greater the cause, the greater the effect,' therefore the greater the weight of the stone the more quickly will it fall, and thus of two stones let fall from the same height, the heavier will reach the ground sooner than the other." Something of this kind, it may be presumed, was the argument of Aristotle and his followers before the age of Galileo: and how on *à priori* principles is it to be refuted? Of course it is disposed of at once by the simple observation that the same force does not produce the same motion in different masses: but independently of some such observation or experiment, it seems to me impossible to deny that it *may be* true, though even an *à priori* philosopher might show that, as other alternatives are conceivable, it is not *necessarily* true. As a matter of historical fact, Galileo refuted it once for all by the "consciously-made experiment" of letting two different weights fall simultaneously from the leaning tower of Pisa.

But it may be said that the above argument is hardly "*definitely* quantitative." Let us then examine Newton's Second Law of Motion as an "immediate corollary" of our *à priori* assumption. Here the cause is "the motive force impressed," and the effect "the alteration of motion." But then the question arises—how are the quantities of this cause and effect to be measured? Newton carefully defines quantity of motion as proportional to *mass* and *velocity* jointly; that is, he measures it by *momentum*. From another point of view it would have been correct to measure quantity of motion by *kinetic energy* or *vis viva*, that is, as proportional to mass and the *square* of the velocity jointly. Further the "alteration of motion" might be measured either with respect to a given time or to a given space. Newton implies the former, and consequently the explicit statement of his second law is that "the *momentum* generated *in a given time* by an impressed force is proportional to that force." Substitute for this "the momentum generated in moving through a *given space*," or "the *kinetic energy* generated in a given time," and the law becomes untrue. Substitute "the *kinetic energy* generated in moving through a *given space*," and we have a law which is true, but not that which Newton asserted as his second law. Now among these four alternatives how is our *à priori* philosopher to decide? He might perhaps analyse them further and show that some of them are inconsistent with the others, and I believe he might reduce the questions to be decided to still simpler ones; but I fail to see (in common, I believe, with everyone who has thoroughly grasped the fundamental principles of rational mechanics) how, without recourse to consciously-made observations or experiments, he could arrive at a certain conclusion.

May we not say then that these great *à priori* principles, whatever value they may have in a "System of Philosophy," are of little avail in any special science, and that the "axioms" of such science, however much they may involve these principles, are not mere "immediate corollaries" therefrom?

If not intruding too much on your space, I am tempted to apply to Mr. Spencer's great principle of the "Persistence of Force" the same mode of treatment as I have applied above to the principle that "effects are proportional to their causes."

Mr. Spencer distinctly refuses to identify this principle with the great physical principle of the Conservation or the Persistence of Energy, the firm establishment of which undoubtedly marks one of the most important epochs in the history of Science. Force, in Mr. Spencer's use of the term, includes numerous species of which energy is but one. I feel sure that every mathematician and physicist would protest against the inclusion under one term of magnitudes of such different kinds as statical force and energy, or the work done by such a force; but not to dwell on this, I believe that Mr. Spencer would certainly acknowledge as one of his species, that which (in my view) is alone properly termed Force, namely, such as can be measured in terms of the weight of a pound or a gramme. What then does Persistence of Force of this kind mean? Does it mean that the numerical sum of the intensities of all the Actions and Reactions throughout the universe is constant? If so, it is untrue: for, to take a simple illustration, if a weight be supported, first by a single string, and then by two strings not vertical, the tensions are quite different in the two cases, and there is no equivalence between those which disappear, and those which are introduced in passing from one to the other. If not, we must take account of the *directions* of our forces, and then, if it mean anything, it appears to be but the expression of Newton's Third Law that "action and reaction are equal and contrary" in this form:—"The algebraical sum of all the forces throughout the universe is persistently zero." To every mathematician, at any rate, this assertion and the assertion that "the sum of the energies of all kinds throughout the universe remains persistently of the same definite numerical amount" are assertions of facts of such different orders, that to class them together is rather to introduce confusion of thought than to establish a grand general principle.

I have offered the above remarks because it appears to me only fair to the author of the article on Herbert Spencer in the *British Quarterly Review* to show that it is felt by others, who have made a study of the fundamental principles of rational mechanics, that his strictures on Mr. Spencer's treatment of those principles are in all essential points fully justified, however much they may wish that the expression of those strictures had been in some instances modified in its tone.

The Park, Harrow, April 20 ROBERT B. HAYWARD

I THINK it is positively due, not only to the writer of the now famous article in the *British Quarterly Review*, but to Newton's memory and to Science itself, that the correspondence which has been going on should not seem to terminate as a drawn game, at any rate in the opinion of some bystanders, who may from their antecedents be presumed competent to judge.

That Mr. Spencer will ever be convinced is, I suppose, hopeless; I at any rate am not going to try to convince him. But I can assure the *British Quarterly Reviewer* that he has my very deepest sympathy in his argument with an antagonist who is at once so able a master of fence as Mr. Spencer, and yet is so intensely unmathematical, it would seem, as to pass from "exact quantitative relation" to "proportionality;" or as to talk of the effect of a force, without defining how the effect is to be measured, without feeling the slightest difficulty.

Nor does it seem that Mr. Frankland, in NATURE, vol. ix., p. 484, is quite justified in his conclusion that the truth lies *between* the two opposite views. And his own view is in fact entirely coincident with the Reviewer's, except, perhaps, on a point which is not relevant to the controversy, viz. how far the experimental proof of the so-called physical axioms is *complete*.

Will it comfort the Reviewer if I tell him some of my own experience? I, too, read Spencer after my degree; and on the first reading of the "First Principles" came to the sad conclusion that I had not understood any mathematics properly; so much fresh light seemed to be thrown on them. I read it again, and more critically, and doubted whether Spencer was quite correct. I read it again, and concluded that he was wrong in his physics and mathematics. I ought to add that I too was, like the Reviewer, A SENIOR WRANGLER

I AGREE so fully with the chief contents of Mr. Frankland's letter (vol. ix. p. 484), that I wish to call his attention to one point in which his letter seems to me calculated to mislead.

He says, "the pure empiricists argue that because certain observed results coincide with the results of calculation, therefore the assumptions on which the calculation was based must be true. Now without doubt the *demonstrative* character of this inference vanishes entirely under Mr. Spencer's searching criticism. But it seems to me that a *high probability* remains."

Now, in the name of pure empiricists, I must protest against our being supposed to think that anything "must be true" in any other sense than that there is a "high probability" of its truth. I cannot refer to a better exponent of our views on this point than Prof. Clifford, to whom Mr. Frankland himself refers. And the idea of our having to thank Mr. Spencer for showing that the inductive proofs of the laws of motion (or of any other physical truths) are not *demonstrative* in any other sense than the above is quite new to us. What Mr. Spencer has done is to bring up instances of this so-called imperfectness in the demonstration as evidences that no *à posteriori* proof of the proposition can exist, when in point of fact they are specially characteristic of such a proof.

Those of your readers who have examined Mr. Spencer's ingenious proof of the second law of motion, contained in his last letter to NATURE (vol. ix. p. 461), will not ascribe my not immediately answering his letter to any difficulty in so doing.

THE AUTHOR OF THE ARTICLE IN THE BRITISH QUARTERLY REVIEW

Lakes with two Outfalls

IN NATURE, vol. ix., p. 485, Mr. Craig Christie begins a letter "to correct a mistake as to a matter of fact:" "Loch-na-Davie, Arran, has *two* outlets, as is correctly represented in the Ordnance map;" and he ends his letter: "I think Colonel Greenwood ought at least to have made himself acquainted with the Ordnance map."

I take the liberty to enclose to you the new Inch Ordnance map of Arran, to which my letter in vol. ix. p. 441 referred. You will see that as "a matter of fact" the map does *not* give two outlets, but only one.

I need not ask for your valuable space in reference to Mr. Christie's own "matters of fact," since my views with reference to them are printed in the *Athenæum* of July 22, 1865. He will see there that I have not only "walked up the north stream from Loch Ranza," but also by Glen Catacol and Glen Dzeven, and a third time from Corrie by Glen Sannox over the water-parting. Also that I have sounded the whole of this little pool of bog-water by walking it, bare-legged, without being over my knees in the deepest part, which was at the south end, where the only outlet is to Glen Iorsa.

I shall have the pleasure to communicate with Mr. Thelwall in reference to his obliging letter.

GEORGE GREENWOOD

[The Ordnance map forwarded to us by Colonel Greenwood gives only one outlet to Loch-na-Davie.—ED.]

As this subject appears to me to possess an interest apart from the issues hitherto in question, I trust you will allow me a little of your space.

From the fact that lakes do not ordinarily occupy the crest of a watershed, it would *à priori* appear more likely that a double outfall, if it exist, should lie in or towards adjacent districts than connected with opposed valley systems. The following instance, which I observed in Norway last summer, is, in view of Colonel Greenwood's letter (NATURE, vol. ix. p. 441), worth mentioning. The lake exhibiting it lies about two miles inland (N.W.) from the elevated coast which faces Trondhjem, and is named Stor Lake; its length—nearly parallel to the Trondhjem fjord—is about seven miles, its greatest breadth about two. Like many Norwegian lakes, it presents a *facies* different to what we are most familiar with in Britain. Instead of occupying a single valley-basin, it consists of a chain of minor basins strung along an axis of depression (probably a pre-existing valley), and each separated from its neighbours by the subsided walls of the valley of which it is the cup-like enlargement. The form of Stor Lake is irregular, with long arms or creeks extended (obliquely to its longer axis) into the mouths of the valleys. In such lakes it might be expected now and then that the effluent waters should pass out at more than one of these channels, and in Stor Lake such is the case. One stream is discharged from one of the component basins, nearly at right angles to the lake's greatest length, the other issues along the depression on which I have said the basins are "strung"—bead-like. The former opening is of post-glacial date, and is superseding the original one for several reasons:—(1) it flows along the strike of a homogeneous bed of schist, whereas the other cuts across beds of various textures, and (2) its volume is greater. Its rival bears evident traces of

progressive attenuation, and is not marked on any published map.

In this case the streams are nearly at right angles to each other when discharged; another instance, however, seems to be furnished in a neighbouring loch, Grön Lake, in which they are collateral. Krefting's map (1868) represents the loch as bifurcating at its north-east end, each of the inlets giving rise to a stream; they seem about two miles apart, are marked by lines of about equal thickness, and flow nearly parallel to the Trondjhem fjord near Mosvigen.

I believe that instances of a like nature with these are by no means rare in Norway. I know at least one lake near Trondjhem, which at a former period seems to have had a double outfall, and many others in which, were the existing outlet dammed by a moraine twenty to fifty feet high, the water would find one or several openings elsewhere.

I have indeed noted several instances of lakes with two outfalls upon Prof. Munch's large map of Norway (1845), but failing to discover any confirmation in other maps, and finding it in other respects unreliable upon matters of such detail, I can assign no value to them.

It would be a fact of curious significance, as bearing upon Prof. Ramsay's theory of the glacial origin of lakes, if most authenticated instances of lakes with several outfalls could be referred to districts which have been traversed by a continuous sheet of glacier ice. When glaciers were confined within valley boundaries, as in Britain, their force was of necessity concentrated along lines, but upon level tracts or plateaux they were free to scoop wherever circumstances favoured erosion. Should it prove that Norway, North America, and Lapland give us the majority of lakes with several outfalls, no other theory can explain the fact.

St. James's Park, S.W. HUGH MILLER

Trees "Pierced" by other Trees

COLONEL GREENWOOD'S answer (NATURE, vol. ix. p. 463) to Mr. J. J. Murphy encourages me to mention a botanical phenomenon which I witnessed in 1865, but have scarcely ever mentioned before for fear of being disbelieved. I was standing on the bank of the little river Evenlode, in Oxfordshire, looking at an old pollard willow trunk about six feet high, when I observed in the decayed wood of the tree an upright sort of staff resembling a dark-coloured old school ruler, and of about that size. I knocked away some of the touchwood above and below, and found my ruler lengthened each way. At the point where it would naturally issue at the top, I found a small twig of undoubted ash, of which the leaves were fully expanded, sprouting up among the branches of willow. Upon clearing away a little more rotten wood I laid bare another ruler, which, like the first, appeared to lengthen upward to the top of the trunk and downward to the ground, but there was no second twig of ash above. The "rulers" were rough where they were totally enclosed by the willow, and had put forth little threadlike rootlets. But the part which I found exposed to the air was smoother and looked like a true branch, but was darker than the usual colour of ash. I afterwards drew the proprietor's attention to the tree, but he could not suggest any explanation. I daresay it is there and in the same condition to this day; if anyone wished it, I could easily describe where it might be found. One explanation I have had offered is, that an ash-seed had fallen down a deep crack in the willow. But there was no sign of such a crack—no crack-like cavity—one of the "rulers" being totally and closely enveloped with the rotten wood, and the other very nearly so. Whether it would have been possible for an ash-seed to germinate in a crack which must have been at least four feet deep and probably much deeper, and was open at the top only and was certainly no larger than the shoot which it formed, is a question I must leave to botanists. Another explanation was, that as ash-roots travel for a considerable distance underground, it was possible that two such roots, finding suitable pabulum in the rotten trunk of the willow, had turned upwards. But this also I must leave to men of science, and notably to Col. Greenwood. T. S.

PROF. TAIT ON "CRAM"

ON Wednesday, the 22nd inst., at the ceremony of capping the Graduates in Arts of Edinburgh University, Prof. Tait gave an address in which he touched on various subjects of Academical interest. On the subject of "Cram" he spoke as follows:—

"It is a mere common-place to say that examination, or, as I have elsewhere called it, artificial selection is, as too often conducted, about the most imperfect of human institutions; and that in too many cases it is not only misleading, but directly destructive, especially when proper precautions are not taken to annihilate absolutely the chances of a candidate who is merely crammed, not in any sense educated. Not long ago I saw an advertisement to the effect:—'History in an hour, by a Cambridge *Coach*.' How much must this author have thought of the ability of the examiners before whom his readers were to appear? There is one, but so far as I can see, only one, way of entirely extirpating cram as a system, it may be costly—well, let the candidates bear the expense, if the country (which will be ultimately the gainer) should refuse. Take your candidates, when fully primed for examination, and send them off to sea—without books, without even pen and ink; attend assiduously to their physical health, but let their minds lie fallow. Continue this treatment for a few months, and then turn them suddenly into the Examination Hall. Even six months would not be wasted in such a process if it really enabled us to cure the grand inherent defect of all modern examinations. It is amusing to think what an outcry would be everywhere raised if there were a possibility of such a scheme being actually tried—say in Civil Service Examinations. But the certainty of such an outcry, under the conditions supposed, is of itself a complete proof of the utter abomination of the cramming system. I shall probably be told, by upholders of the present methods, that I know nothing about them, that I am prejudiced, bigoted, and what not. That, of course, is the natural cry of those whose 'craft is in danger'—and it is preserved for all time in the historic words, 'Thou wert altogether born in sin, and dost thou teach us?' I venture now to state, without the least fear of contradiction, a proposition which (whether new or not) I consider to be of inestimable value to the country at large:—Wherever the examiners are not in great part the teachers also, there will cram to a great extent supersede education. I need make no comment on this, beyond calling your particular attention to the definite article which twice occurs in the sentence, and which gives it its peculiar value.

"I said, in my former address [eight years ago], that 'coaching' seems quite natural to all who are engaged in it, and, in particular, that it did so to myself more than twenty years ago. This shows that it is possible that something akin to the results of the profound speculations of Riemann, Helmholtz, and others, may hold in the moral if not in the physical universe. It is probably new to most of my audience to hear that very great authorities are as yet in doubt whether the properties of space itself are the same in different localities; whether, in short, in our rapid flight through space, we may not be insensibly getting into a region, our existence in which will involve a gradual change of form, in order that our physical substance may continue to fit the varying circumstances of our position. Assume that something like this holds in the world of mind, and you see at once how the same man may, while residing in Edinburgh, honestly denounce certain methods as wholly pernicious which a few years' residence in Cambridge may invest in his eyes with a perfection more than human. I do not say that this is an explanation; but the analogy is at least worthy of remark; and I leave further discussion of it to my old friend Mr. Todhunter, who, living in the middle of that singular region, tells me he thoroughly agrees with me in my main arguments against examinations, and then soundly rates me for my mode of propounding them."

After advocating the restoration of the B.A. degree to Edinburgh University, Prof. Tait spoke in forcible terms

against the centralisation of our various Universities, Licensing Boards, &c, "with its inevitable acolyte cram." He illustrated in an original and striking way what he thinks would be the inevitable result of centralisation, by referring to the dead and motionless uniformity which must be the result of the degradation of energy. Prof. Tait drew a ludicrous yet melancholy picture of what would be the results of universal uniformity in the social world.

"The application of these ideas," he said, "to political and social questions, among which of course comes University centralisation, is not far to seek. What would the world of men be without what we may call 'social entropy'? Everyone would then be his own farmer, baker, butcher, brewer, banker, boot-black, &c.—all would be at the same dead level—no possible help from one to his neighbour, even if it could be required; no distribution of tasks, and therefore (in every department) that endless waste which is inevitable in operations conducted on a petty scale. No possibility of that mutual reliance and assistance which forms the friendships we delight in, none of that variety which is the real charm of life—no idea which would not simultaneously strike every unit of the race—no news, no books—nothing but sameness! None of the pleasure of being able to assist struggling worth, none of gratitude for generous aid. Nay, we might pursue it further. No difference of temper, character, tendencies, age, sex—a state lower than the lowest known in vegetation; but here the end must come. Or, to take a somewhat different point of view (though the basis is absolutely the same, for oscillation implies entropy), what if everything were always at its average value? Never absolutely either fair or rainy weather, clear or cloudy, calm or stormy, hot or cold; but a dead average. Never either absolutely day or night; no tides, no seasons; men never either absolutely awake nor absolutely asleep—continually in a semi-lethargic state—half happy, half discontented; half playful, half serious—neither running, walking, standing, sitting, nor lying, but a perpetual average. No catastrophes such as a birth, a marriage, or a death—no distinction between man and man—nothing of that variety which is the law of nature. Eternal, hideous, intolerable sameness, by necessity devoid of all capacity for action: the human race turned into a set of Nürnberg toy-solders, all cast in the same mould, of the same base material, and all similarly bedaubed from the same glaring paint-pots, and moving on the same lazy-tongs with the same relative velocities. No one to advise you in a difficulty, no one in whose superior strength of mind or body you could confide; nothing around you except what you feel must be but the image of yourself (as you will early have learned introspectively to look at it)—mean, sordid, and grovelling! No one whom you can respect, none to trust—all, like yourself, vile and despicable! Here I would gladly say—'Enough of such horrors,' and quit the disgusting theme. But, unfortunately, the application has still to come. It will be found very pertinent to many things which have been of late evolved from the innermost consciousness of statecraft, and hailed, with altogether inexplicable delight, by what seemed (till lately) to be at least a numerical majority of the representatives of our countrymen."

Prof. Tait then referred to the late Prof. Forbes and the recent discussion concerning his character and work. For what Prof. Tait has to say on this subject we must refer our readers to his address, which is printed in full in the *Scotsman* of the 23rd inst. He then spoke of the scheme for extending Edinburgh University, and the facilities which would thereby be acquired for teaching Science practically, as it ought to be taught, and thus tend to extinguish "paper-science," a term which "conveys to all who are really scientific men an impression of the most unutterable contempt." In conclusion, Prof. Tait referred to the difficulties attending the work of his own class, that of "Natural Philosophy," arising from the want of adequate means. He hopes to be able, at least, to put the Natural Philosophy Department in Edinburgh University on a proper footing for his successor.

THE SOIRÉE OF THE ROYAL SOCIETY

On Wednesday, April 22, the first soirée of the Royal Society since their removal into their new apartments was given by the President, Dr. Hooker, and came off with the greatest *éclat*. There was a remarkably good display of scientific apparatus, and we think that the interdependence of the man of Science and of the manufacturer of instruments is at no time better exemplified than on occasions like the present. The apartments devoted to the purposes of exhibition were thronged by the most eminent in the various branches of Science—it might have been said with reason that a considerable fraction of the nation's mind had centred for the time being in the rooms at Burlington House. Not as an unhealthy sign either did we regard the presence of Archbishop Manning and the attention shown towards that divine by scientific men of the very opposite poles of thought.

Of the objects of interest displayed in the six rooms devoted to this purpose we can here only give details of the more prominent. In the first room several maps and photographs were exhibited by the Royal Geographical Society; also some splendid pieces of glass-work by Messrs. Chance, consisting of a dioptric fixed light (4th order) with nine prisms and six rings of lenses in four panels, a segment of a dioptric totally reflecting mirror first proposed by Mr. Thomas Stevenson, C.E., a dioptric holophote designed by the same engineer, and a lamp-burner designed by Mr. J. N. Douglass, C.E., with six concentric wicks. This burner can be used either for colza oil or for petroleum. The President exhibited also in this room some interesting objects from the Kew Museum. Amongst these we noticed some fossil copal gums from Zanzibar, carved cocoa-nut shells from the Fiji Islands, a vase made from the ash of *Moguilea utilis*, mixed with clay, from Parà, and different chemical and medical products from species of *Eucalyptus*.

In the second room Mr. Crookes exhibited his experiments showing the attraction and repulsion accompanying radiation. The pendulum described by Mr. Crookes in his communication to the Society was exhibited under various forms, and the experiments excited the liveliest interest. Here also Dr. C. J. B. Williams exhibited some new ear-trumpets, and Messrs. Whitehouse and Latimer Clark an electrical recorder for registering time, speed, distance, and number of passengers inside and out in tram-cars and omnibuses. This information is registered in four parallel columns in red ink on long strips of paper, by automatic pens.—Mr. Vernon Heath exhibited some autotype landscapes, and the president some Tappa dresses from Fiji, which reminded us strongly of the ornaments placed in our fire-stoves during the summer. Here also we were shown a microscope by Messrs. Powell and Lealand, with a $\frac{1}{80}$ immersion objective and the eternal Podura scale.

In the third room, the Entrance Saloon, were some exquisitely coloured drawings of the flora of Brazil, and landscapes by Miss North; likewise some coloured drawings of New Zealand birds, exhibited by Dr. W. Lawry Buller. The pair of new Paradise Birds collected by Signor D'Abertis* in New Guinea, promised by Dr. Sclater, was not exhibited.

In the fourth room, the Reading Room, Dr. Tyndall exhibited the apparatus (already described in our columns) for showing the stoppage of sound by a non-homogeneous mixture of air and vapours, and also experiments illus-

* See NATURE, vol. viii. p. 305.

trating Savart's observations on the action of sound on a jet of water. Dr. J. H. Gladstone exhibited some photographs of fluorescent substances. Bottles containing fluorescent liquids, such as æsculin or quinine di-sulphate, appear in the photographs nearly as black as a bottle filled with ink; similarly, labels written with such liquids, although the characters are ordinarily invisible to the eye, show up their designs when photographed. In this room were to be seen also photographs of the Naples Aquarium, exhibited by Mr. W. A. Lloyd, and one of Dr. Dohrn's Zoological Station at Naples, lent by Mr. Darwin; likewise some lithographed plates of recent Foraminifera from the Abrolhos Bank, exhibited by Profs. W. K. Parker and Rupert Jones. Mr. J. Norman Lockyer exhibited a series of photographs of metallic and solar spectra enlarged by Messrs. Negretti and Zambra from photographs taken by his new method of comparing spectra by means of a perforated shutter sliding in front of the slit of the spectroscope. In this room the new sextant devised by Capt. J. E. Davis was exhibited. This instrument, which will be found particularly useful in night observations, permits the taking of a series of observations without reading off each observation; this being accomplished by the adaptation of a micrometer movement to the tangent-screw, and the application of indicators to the arc of the instrument. Mr. Alfred Tribe here exhibited some specimens of metals (palladium, copper, &c.) which had become agglomerated in a most remarkable manner by hydrogenisation; under ordinary circumstances the metals shown existed in the form of fine powders, but, as soon as charged with hydrogen, become agglomerated.

The fifth room, or Principal Library, is by far the largest apartment of the suite. Mr. C. V. Walker's electrical apparatus for carrying out the "block system," or "space intervals," between trains on the South-Eastern Railway, was here displayed. Messrs. Tisley and Spiller exhibited their compound pendulum apparatus in action, and distributed cards with the exquisite curves described upon them. This firm exhibited also the beautiful triple combination double-image prism belonging to Mr. Spottiswoode. Mr. E. B. Tylor's ingenious apparatus for illustrating refraction (already described in these columns) was exhibited in this room.* We observed also some splendid gold crystals exhibited by Mr. W. C. Roberts, Chemist to the Mint; Mr. W. H. Barlow's "Logograph," a recording instrument for showing the pneumatic action accompanying the exercise of the human voice; and a pair of gyrostals exhibited by Prof. Sir William Thomson. Messrs. Negretti and Zambra exhibited their ingenious thermometer for recording deep-sea and atmospheric temperatures, already described in NATURE. Mr. John Browning exhibited a good collection of apparatus. Mr. G. P. Bidder's micrometer, a most ingenious device for observing the transit of very faint stars, in which the spider lines, capable of the usual micrometer movements, are illuminated by a side light, and are reflected into the eye-piece by a mirror, thus appearing bright upon a dark ground, and by interposing coloured glasses between the lamp and the spider lines can be coloured at pleasure. Sir Charles Wheatstone's new photometer is well worthy of notice: the screen slides along the divided scale and its motion causes the increased overlapping of two sliding wedges of neutral-tint glass. The light is looked at directly through a hole in the screen, and the latter moved along the scale till the light just ceases to be visible. We noticed also a micro-spectroscope of very good definition, showing the absorption spectrum of cantharides. Mr. Apps exhibited a model and diagram of a fireproof building, and a model of an improved apparatus for indicating the speed of revolving shafts, both being the inventions of Sir David Salomons. The plan for rendering buildings fireproof consists in laying on water-pipes between the walls and floors of the building, these pipes being self-acting by means of fusible-metal plugs or electrical communications. The last-named model is an application of the ordinary governor balls, which are connected with the shaft, and by a system of levers, with an index, which moves up a graduated scale. A double-action spectroscope with a divided object-glass, made by Grubb, of Dublin, was shown and explained by Lord Lindsay; this instrument is intended by its owner to be attached to a large equatorial for the observation of stellar spectra. Among other noticeable things in this room we may mention the Megohm, one million British Association units, by Messrs. Elliott Brothers; Mr. George Barnard's highly artistic water-colour drawings and the copies of sacred Icons of the Greek Church in Russia, and photographs by Mr. John Leighton. Col. Stuart Wortley's photographs from life are high examples of art, and the group of living corals (*Astroides calicula*) from the Bay of Naples, exhibited by the Crystal Palace Aquarium Company, attracted large numbers of admirers by their beauty. At 10 o'clock Dr. R. Norris, of Birmingham, exhibited in the meeting-room experiments to illustrate a form of contractive energy which displays itself in various substances. Among other things the Doctor showed that the statement that india-rubber *contracts* by heat is incorrect; this substance, it is true, contracts in the direction of its length, but it expands in breadth at the same time, thus resembling the so-called contraction of muscular fibre.

In soirées of this kind experiments illustrative of new chemical discoveries are generally "conspicuous by their absence." This surely cannot be due to the fact that the science does not permit of public demonstration; it arises rather from the "messy" nature of the materials employed by chemists, thus precluding the introduction of chemicals into such rooms as are devoted by the Society to their gatherings. We are of opinion that in not fitting up and adding to their now noble apartments a laboratory, an omission has been made which may be regretted in the future.

* We should recommend lecturers using this apparatus to see that the wood is well seasoned; the one exhibited soon ceased to act satisfactorily, owing to the warping of the board.

THE LECTURES AT THE ZOOLOGICAL SOCIETY'S GARDENS

II.

IN the second and third of his lectures On the Geographical Distribution of the Mammalia, delivered on the Tuesday and Friday of last week, Mr. Sclater described in detail the ranges of the different orders of terrestrial mammals; and to avoid unnecessary repetition, employed the well-known system of division of the earth's surface, proposed before the Linnean Society in 1857, from a study of the bird class, according to which there are six regions—(1) The *Palæarctic*, including Europe, Africa north of the Atlas Mountains, and Northern Asia. (2) The *Ethiopian*, including all Africa south of the Atlas Mountains, and the southern part of Arabia. (3) The *Indian*, including Asia south of the Himalayas, Southern China, and the Indian Archipelago. (4) The *Australian*, including Australasia. (5) The *Nearctic*, including North America down to the centre of Mexico; and (6) The *Neotropical*, including South and Central America. The following is a summary of his remarks.

Among the monkeys the anthropoid apes inhabit equatorial Africa, where the gorilla and chimpanzee are found; Sumatra and Borneo are the home of the orang outang; while the eastern portion of India, Burmah, and the Indian Archipelago constitute the habitat of the various species of gibbon. The catarrhine monkeys, including the green monkeys (*Cercopitheci*), and the macaques inhabit Africa and India respectively; the latter, however, extending into Africa north of the Sahara, as far as Apes Hill and the Rock of Gibraltar. The platyrrhine monkeys, among

which are the spider monkeys, the howlers, and the marmosets, are found in the Neotropical region, except in its southern and western parts. The lemurs are mostly confined to the island of Madagascar, some few inhabiting Eastern India, and two forms occurring in Western Africa.

Among the large order of the Carnivora the lion is a denizen of the forests of the Ethiopian region, and spreads slightly beyond it into India. The tiger is found in the Indian region, and spreads up into China and Central Asia, where its coat becomes coarser in texture. The leopard is distributed over the districts of the lion and tiger; it is also found in Borneo and Ceylon, whilst the lynx occurs in the Neartic and Palæarctic regions. The dogs are cosmopolitan, though it is doubtful whether the single form of Australia has not been introduced by man in early times. The bears inhabit the Palæarctic, the Nearctic, and the Indian regions, being also found in the Andes of Peru.

Among the odd-toed, or Perissodactylate Ungulates, the horses and asses are strictly Old-World forms, the exact place of origin of the former being uncertain. The asses are spread over the Indian and Ethiopian regions. The tapir is very aberrant in its distribution, one species appearing only in Sumatra and the Malay Peninsula, while in the northern portion of South America and Central America three others occur. The rhinoceroses are from the Indian and Ethiopian regions only, the Asiatic species all being now or having lately been exhibited in the Zoological Gardens. Those from Africa are less perfectly known, only two species having been accurately determined.

Among the even-toed, or Artiodactylate Ungulates, the camels are very peculiar in their habitats, the Llamas of the Andes and the camels of Africa, Arabia, and part ef Russian Asia being the only known forms; those from the last-named locality being the only known wild true camels of the present day. The giraffe is purely Ethiopian. The bison in North America represents the oxen of the Indian region, which in Africa and Arabia are in great measure replaced by the antelopes, so varied in form and size. The Cervidæ are not found in the Ethiopian nor Australian regions. The hippopotamus inhabits all the large rivers of Africa, the smaller species being found in and about Liberia. Of the Swine-family the peccaries are the representatives in the Neotropical region, whilst the quaint Wart-Hog and Red River Hog are exclusively African.

The hyrax, or coney of Scripture, whose zoological position is so uncertain, is found in Arabia and parts of Africa only.

There are only two species of elephant known, the Indian being from the Indian region, and the African from the Ethiopian. In very recent times they abounded in Siberia, and earlier still in many other parts of the world.

The Neotropical region abounds in peculiar Edentate animals, as the armadillos, sloths, and ant-eaters. The scaly ant eaters or Pangolins, and the ant-bears or Orycteropus, are found, the former in India and Africa, the latter in Africa only.

Among the Insectivora, the peculiar Solenodon inhabits St. Domingo; the gilded mole, South Africa; the Tenrec, Madagascar; and the Tupaias, the Malay districts.

Among the Rodentia the porcupines, divided into two well-distinguished sub-families, inhabit, one the Old and the other the New World. The Neotropical region, however, is the head-quarters of the *Hystricidæ*; the capybara, together with the agoutis, and numerous other forms being from that locality. There are also found the chinchilla and viscacha. The beaver abounds in the Nearctic region, and used to do so in Europe, till the increase of population has almost exterminated it. The hare and rabbits have a wider distribution, as have also the squirrels.

It will be noticed that Australia has been scarcely mentioned in the above remarks, and that the dog which is spoken of in connection with it is not known certainly to be indigenous. This is because the mammalian fauna is almost entirely represented by animals of the Marsupial order, the kangaroos, bandicoots, phalangers, wombat, koala, thylacine, and dasyures being peculiar to it and Van Dieman's land. Among Marsupialia the group of opossums is only found in the Neotropical region, extending quite through Mexico into the United States.

The Monotremata, including only the duck-bill or ornithorhynchus and the echidna, are confined to New South Wales and Tasmania.

(*To be continued.*)

THE FLUCTUATIONS OF THE AMERICAN LAKES AND THE DEVELOPMENT OF SUN-SPOTS

IN the course of an investigation, undertaken in my capacity as Geologist to the B.N.A. Boundary Commission, as to late changes of level in the Lake of the Woods, bearing on the accuracy of certain former surveys, I found it desirable to tabulate the better-known fluctuations of the great lakes for a series of years as a term of comparison. The observations of secular change in Lake Erie are the most complete, and these, when plotted out to scale, showed a series of well-marked undulations which suggested the possibility of a connection with the eleven-yearly period of sun-spot maxima. A comparison with Mr. Carrington's diagram of the latter confirmed this idea, and as I do not remember to have seen these phenomena connected previously, I have been induced to draw out the reduction of both curves here presented, and the table of the height of water in the lakes.

The changes of level affecting the great lakes are classed as follows by Colonel Whittlesey, who has given much attention to the subject:—

1. General rise and fall, extending through a period of many years, which may be called the "Secular Variation."
2. Annual rise and fall within certain limits, the period of which is completed in about twelve months.
3. A sudden, frequent, but irregular movement varying from a few inches to several feet. This is of two kinds, one due to obvious causes, such as winds and storms; another, described as a slow pendulum-like oscillation, has been somewhat fully discussed by Whittlesey in a paper read before the American Association at its last meeting, and is due probably to barometric changes in the superincumbent atmosphere.

The first class is the only one directly included in the present inquiry.

I.—*Table of Great Lakes.*—In Mr. Lockyer's new work on Solar Physics, chap. xxvi., entitled "The Meteorology of the Future," exhibits the parallelism of periods of solar energy, as denoted by the outburst of sun-spots, with the maximum periods of rainfall and cyclones, and for the southern hemisphere, by a discussion of his own and Mr. Meldrum's results. In the table (p. 505) I have arranged the more accurate numerical observations of the height of the lakes from registers kept for the last few years, in a method similar to that there adopted.

Prof. Kingston's observations of Lake Ontario were taken at Toronto, and measured upward from an arbitrary mark. They extend from the year 1854 to 1869, and include the minimum periods of 1856 and 1867, and the maximum of 1860. Taking the mean annual level for

each minimum and maximum epochal year, and one year on each side of it, as is done by Mr. Meldrum, and deducing a mean from each of three tri-yearly periods,

Table showing the height of water in the American Great Lakes, measured upward from an arbitrary mark, for the years surrounding periods of maxima and minima in the occurrence of Sun-spots.

Sun-spot Periods.	Year.	Lake Ontario, from Prof. Kingston's observations. Yearly means.	Lake Ontario, from Prof. Kingston's observations. Tri-yearly means. Mean of maximum periods in Lakes Ontario, Superior, Michigan, and Erie, from U.S. Lake Survey Obs. 29·61
Mean of minimum ,, ,, ,, ,, ,, ,, 14·97
Difference 14·64

The measurements are in inches and decimals.

the agreement is close between the solar periods and those of fluctuation in the lakes.

The remaining observations are those of the U.S. Lake Survey, and include only one period each of maximum and minimum in solar spots. The measurements of the U.S. Survey are reckoned *downwards* from a mark representing the high water of 1838 in each of the lakes, but in the table here given they have been reduced so as to read upwards from an arbitrary line chosen 4 feet below that datum. They are thus rendered more intelligible and made to agree in sense with Prof. Kingston's measurements.

The result is the same in each of the lakes, only differing in amount by a few inches. A mean deduced from the U.S. Lake Survey observations in Lakes Superior, Michigan, Erie, and Ontario, gives a difference between the years surrounding the maximum of 1860 and the minimum of 1867 of 14·64 inches in favour of the former.

2. *Diagram of Curves.*—The curve representing the fluctuation of Lake Erie from 1788 to 1857 inclusive is constructed on a careful discussion of the evidence collected by Col. Whittlesey and given by him most fully in the "Smithsonian Contributions to Knowledge" for 1860.

From 1788 to 1814 there are no accurate measurements to any well-recognised datum line, and I therefore give below the measurements and approximations on which the general curve for these years has been constructed. The description of the fluctuation of the lake will be seen in many cases to apply with verbal accuracy to the sun-spot curve.

"1788—1790. By tradition derived from the early settlers very high; according to some as high as 1838, but this is doubtful.

"1796. By the first emigrants and surveyors reported as very low—5 feet below 1838.

"1797. Rising rapidly.

"1798. Water continues to rise, but 3 feet below June 1838.

"1800. Very high; old roads flooded.

"1801. Still high.

"1802. Very low; reported by old settlers as lower than 1797.

"1806. Very low; reported by old settlers as lower than 1801—2, and declining regularly to 1809—10 when it reached a level by many considered as low as that of 1819.

"1811. Rise of 6 inches in the spring over 1810, by measurement, and a fall of 2 inches.

"1812. Rise of 14 inches in spring over 1810, by measurement, and a fall of 3 inches.

"1813. Rise of 2 feet 2 inches in spring over 1810 by measurement.

"1814. Rise of 2 feet 6 inches in spring above general level of 1813."

From 1815 to 1833, both inclusive, occasional measurement to fixed data exist; the supplementary notes are here given.

"1815. Rise of 3 feet above average level of 1814. (This statement is not confirmed by an actual measurement made in August, and is probably exaggerated).

"1816. Water still high, but falling, and continued to fall till 1819.

"1819. Lowest well-ascertained level of the waters in Lake Erie.

"1820. Stated to be in August as low as 1819.

"1821. Rising.

"1822. Rising; in the spring 4 feet below June 1838.

"1823. Rising; in the spring 3 feet 3 inches below 1838.

"1824. Rising gradually.

"1825. Rising; lowest level 3 feet below June 1838.

"1826. Rising; lowest level 2 feet 10 inches below June 1838.

"1827. About the general level of 1815.

"1829. Water still rising.

"1830. General level same as 1828.

"1831. Lower than last year; yearly change at least 3 feet.—Col. Whiting. (Probably an error as this would place the water unprecedentedly low. Col. Whiting probably ascertained that the lake was falling and erred in taking some former high-water mark for that of the preceding year).

"1832. General average 2 feet 10 inches below June 1838.

"1833. General average 3 feet 2 inches below June 1838."

From this date to 1857 many actual measurements are given by Whittlesey, and from these the curve for those years has been constructed. The whole of the observations are reduced as nearly as possible to the average level for each year by comparison with a mean annual curve for about 10 years constructed from monthly averages of bi-five-day means given by the U.S. Lake Survey. 1859 to 1869 both inclusive are from yearly means derived from continuous observations at Cleveland by the U.S. Survey. 1871 to 1873 are from information kindly furnished by Gen. Comstock, Director of the Lake Survey. I have no data for 1870.

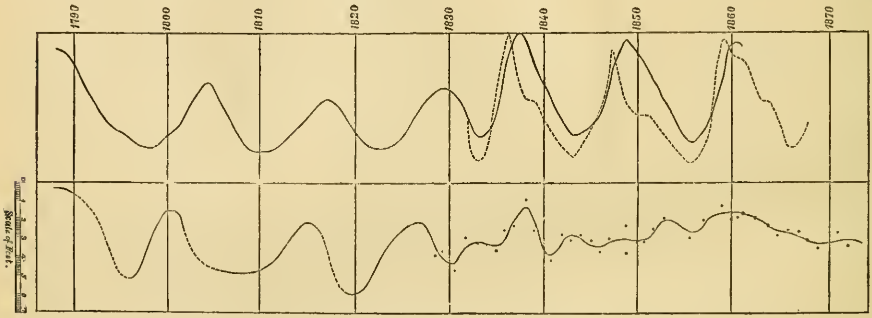
The earlier and less systematic observers of the fluctuations of the lakes would scarcely give attention to any but the more important changes of level, and it is possible that these in many cases may have been exaggerated in amount. It would seem improbable, however, from the

number of observations which have come down to us, that any variations of importance have escaped notice.

In the upper part of the diagram, the unbroken line represents Carrington's curve founded on the number of sun-spots. The broken line is a reduction of a mean curve based on the area of the spots given by De la Rue, Stewart, and Loewy in the Philosophical Transactions for 1870; and is introduced as showing the solar periods to a later date.

3. *General Remarks.*—The first four maxima of sun-spots represented in the table being separated by long intervals of years with few spots, and not being very intense, would appear to have been closely followed by L. Erie. More especially 1837, the year of greatest known intensity according to both spot curves (333 new groups of spots according to Schwabe), was marked in its effects on the lakes, giving rise in 1838 to the highest recorded level of the waters in Erie and Ontario, and probably also in Superior, though here the data are not so certain. The high-water mark of 1838 has since been employed as the datum to which all the measurements of the Lake Survey are reduced.

The three last periods of maxima of sun-spots are extreme, and the intervals characterised by their deficiency so short that the lakes seem to have been unable to follow them as closely as before. One period of high water being to a great extent merged in the next, and resulting in a general high state of the lakes for the last thirty years, which may be connected with the Wolfian Cycle of fifty-six years in the development of sun-spots. The lakes do not seem to have responded to the maximum of 1848, but by a reference to the curve of area of sun-spots, it will be seen that the intensity of this period was not so great as of those on either side of it, and the period of maximum was maintained for a very short time only. The important sun-spot maximum of 1859-60 was evident in its effect on the lakes even at their present general high level. With regard to the Lake of the Woods the data are slight, but it may be mentioned that this lake is known to have been very low in 1823, and in 1859 to have attained a point which it has never touched since, and which is about 3 feet higher than the present level. The lake is also known to have been for a good many years higher than usual, and at least one well-marked high water took place between 1823 and 1859, which may very probably have been synchronous with that of 1838 on the great lakes.



Comparative Diagram of the Fluctuations of Lake Erie, and Periods of greater or less Solar Activity as indicated by the occurrence of Sun-spots. 1. Solar Spot Curves. 2. High Water, June 1838. 3. Lake Erie.

This lake derives its water from the western slope of the same Laurentian range which feeds Lake Superior.

The correspondence between the periods of maxima and minima in solar-spot cycles and in the fluctuation of the great lakes, though by no means absolute, seems to be sufficiently close to open a very interesting field of inquiry, and to show the extension of the meteorological cycle already deduced by Messrs. Meldrum and Lockyer for oceanic areas in the southern hemisphere, to continental ones in the northern.

The great lakes in their changes of mean yearly level probably show a very correct average of the rainfall over a large area, and thus indicate the relative amount of evaporation taking place in different seasons. It is to be observed, however, that the actual mean annual outflow of the lakes would be a better criterion, and that from the form of the river valleys giving exit to the waters, this must necessarily increase in a much greater ratio than the measured change of level in the lake itself. It is much to be desired that such observations should be systematically made. The occurrence of seasons of great activity of evaporation and precipitation, as indicated by the lakes synchronously with those of maximum in solar-spot production, would tend to confirm the opinions previously formed as to the coincidence of the latter with periods of greater solar activity. Wolf, as quoted by Chambers, states from an examination of the Chronicles of Zurich, "that years rich in solar spots are in general drier and more fruitful than those of an opposite character, while the latter are wetter and stormier than the former." Gautier, from a more extended series of observations, including both Europe and America, has deduced an exactly opposite conclusion, which, from the evidence of the great lakes, would appear to be the correct one.

It is quite possible, however, that both may be true (see "Solar Physics," p. 430). The great lakes lying at the base of the Laurentides, where moisture-bearing winds from the southward and westward are interrupted in their course, and meet with cold currents journeying over these hills from the north, are essentially in an area of precipitation, and greater precipitation would here be the natural result of greater solar energy. In other regions excessive evaporation may result from the same cause, and this may account for the gradual desiccation which on the authority of many observers is going on at present over great areas of the inland plains of the west.

The observations here given cannot be accepted as conclusive, but derive additional importance from the large area which they represent, and may suggest more systematic investigation of the subject, and the accumulation of accurate observations, which in the course of years may lead to results of greater value.

G. M. Dawson

POLARISATION OF LIGHT *
VIII.

A QUARTZ plate cut parallel to the axis, when examined with convergent light, gives curves in the form of hyperbolas. These curves are wider in proportion to the thinness of the plate, but if the plate be thick enough to render the curves moderately fine, the colour becomes very faint. They may, however, be rendered distinct by using homogeneous light. The dark and light parts exchange positions when the analyser is turned through 90°. Two such plates with their axes at right angles to one another give coloured hyperbolas perfectly visible with the white light. Plates of Iceland spar exhibit similar phenomena, but the lines and curves are far more closely packed.

If the plate be cut in a direction inclined at 45° (or at any angle differing considerably from 0° or 90°) to the axis, the curves are approximately straight lines perpendicular to the principal section of the plate. Two such plates placed with their principal planes at right angles to one another give straight lines bisecting the angle between the principal planes. On this principle Savart constructed the polariscope which bears his name. It consists of two such plates and an analyser, and forms a very delicate test of the presence of polarisation. The lines are, of course, always in the direction described

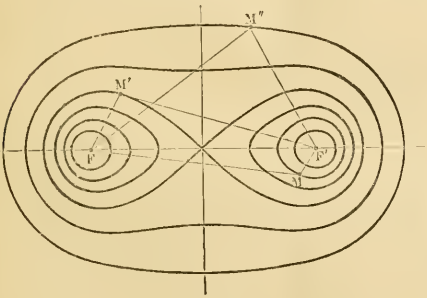


FIG. 26.

above, and the delicacy of the test increases in proportion as their direction becomes more and more nearly perpendicular to the original plane of vibration.

Bi-axal crystals exhibit a more complicated system of rings and crosses, or brushes as they may in this case be better termed. If such a crystal be cut in a direction perpendicular to the line which bisects the angle between the two optic axes (or the middle line, as it is called), the extremity of each of the axes will be surrounded with rings similar to those described in the case of the uni-axal crystals. The larger rings, however, are not strictly circles, but are distorted and drawn out towards one another; those which are larger still meet at a point midway between the centres, and form a figure of 8, or lemniscata; beyond this they form curves less and less compressed towards the crossing point, and approximate more and more nearly to an oval (see Fig. 26).

The vibrations of the two rays emerging from any point of a bi-axal crystal are as follows:—Of the two rays produced by the double refraction of a bi-axal crystal neither follows the ordinary law of refraction; but one does so more nearly than the other, and is on that account called for convenience the ordinary ray. And if through any point of the field of view we draw two lines to the points where the optic axes emerge, the directions of vibration of the two rays will be those of the bisectors of the angles made by the two lines. If, therefore, the crystal be so placed that the line joining the extremities of the two axes coincides with the plane of vibration of either polariser or analyser, it is not difficult to see that there will be a black cross passing through the centre of the field, with one pair of arms in the line joining the extremities of the axes and the other pair at right angles to it. But if the plate be turned in its own plane round the central point, the points, for which the vibrations are parallel or perpendicular to those of the polariser or analyser, will no longer lie in straight lines passing through the centre, but will form two branches of a hyperbolic curve, passing respectively through the extremities of the optic axes.

If the analyser be turned round, the dark hyperbolic brushes, or the black cross, will undergo the changes analogous to those shown in the cross in the case of uni-axal crystals; but the most interesting effects are those seen when the polariser and analyser are crossed, and the crystal is turned in its own plane.

The angle between the optic axes in different kinds of crystals varies very much; in those where the angle is small it is easy to exhibit both at once in the field of view, but in others where the angle is large it is necessary to tilt the crystal so as to bring the two successively into view. In the latter case the crystal is sometimes cut in a direction perpendicular to one of the axes. The rings are then nearly circular, especially towards the centre, and in that respect they resemble those of a uni-axal crystal;

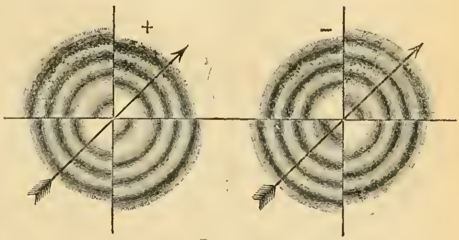

FIG 27.

but the character of the specimen can never be mistaken because the rings are intersected by a black bar, or two arms in the same straight line, instead of by four arms at right angles to one another, as would have been the case if the crystal had been uni-axal. The following are the angles made by the optic waves in a few crystals:—

	°	′
Carbonate of lead	5	15
Saltpetre	5	20
Talc	7	24
Titanite	30	0
Borax	28	42
Mica	30 to 37	0
Carbonate of Ammonia	43	24
Topaz of Brazil	49 to 50	0
Sugar	50	0
Gypsum	57	30
Felspar	64	0
Topaz of Aberdeen	65	0
Oxyde of Lead	70	25
Cyanite	81	48
Chrysolite	87	56

These angles are determined by placing the crystal for an examination into an apparatus adapted to show the rings, and attaching it to an arm whereby the plate can be turned about an axis in its own plane. The axis is furnished with a circle divided into degrees and seconds, and an index. If this axis be horizontal, the plate is so

* Continued from p. 466.

placed that the line joining the centres of the two systems of rings is vertical, and the crystal is first turned so as to bring one centre into the centre of the field of view (usually marked by cross wires); the index is then read, and the crystal turned so as to bring the centre of the second system of rings to the centre of the field. The index is again read, and the difference of the two readings noted. This, however, gives not the true angle of the optic axes, but the apparent angle in air, that is, the angle between the rays as affected by refraction on emerging from the crystal. (See Fig. 27.)

In some crystals the optic axes have different angles of inclination for the different rays of the spectrum. Of this titanite or sphene is an example. All rays have a common middle line, and lie in the same plane, but the optic axes for the red rays are more widely separated than those for the blue, and consequently the part of the field which would exhibit a dark brush if red light were used is deprived of the red rays but not of the blue. The brushes, therefore, appear broader than with ordinary crystals, and are tinged with blue on the edges farthest from the middle point, and with red on the edges nearest to it. It is said that a similar distribution of the optic axes, or its opposite in which the red rays are least separated and the blue most, is found in all crystals belonging to the rhombic system.

In other crystals, the axes all lie in one plane, but all have not the same middle line, so that the two ring systems are unsymmetrical. This is the case with borax. In others the optic axes for different colours lie in different planes, all of which pass through the middle line.

Lastly, we may mention the crystals brookite and tartrate of ammonia soda and potash, in which the optic axes for the two extremities of the spectrum lie in planes at right angles to one another, both passing through the same middle line. If the systems of rings be examined with light which has been so widely dispersed that the portion illuminating the field in any given position is practically monochromatic, and the position of the instrument shifted through the different parts of the spectrum (or what is more convenient, if the different parts of the spectrum be successively thrown on the polariscope by means of a totally reflecting prism), the optic axes will be seen to draw gradually together until the figure closely resembles that of a uni-axal crystal; after which the axes open out in a direction at right angles to the former, until they have attained their greatest expansion. This experiment requires a strong light, but it is instructive, as showing the exact distribution of the optic axes for different rays.

In some bi-axal crystals, notably in gypsum, the distribution of the optic axes varies with the temperature. When the crystal is heated the angle between the optic axes diminishes until the crystal appears uni-axal; with a further increase of temperature the axes again open out, but in a direction at right angles to the former. When the crystal is cooled the axes generally resume their original directions. Sometimes, however, when the heating has been carried to a great degree, or has been continued for a long time, the axes never completely return to their normal condition; and in such a case the crystal may appear permanently uni-axal. Such an appearance, when permanent, has been considered a test of former heating; and this phenomenon, when presented by crystals found in a state of nature, may be taken as evidence that the rocks in which they have been formed have been subject to high temperatures.

In the production and examination of the rings hitherto described, we have used light which has been plane-polarised and plane-analysed; but there is nothing to prevent our polarising the light or analysing it circularly, or indeed doing both.

If a quarter-undulation plate be placed between the polariser and the crystal to be examined, with its axis inclined at 45° to the plane of original vibration, the light will fall upon the plate in a state of circular polarisation; and as the polarisation will then have no reference to any particular plane of vibration, the black cross will disappear. A system of rings will be produced, but they will be discontinuous. At each quadrant, depending upon the position of the analyser, the rings will be broken, the portions in opposite quadrants being contracted or expanded, so that in passing from one quadrant to the next the colours pass into their complementaries. If either the direction of the axis of the quarter-undulation plate be changed from 45° on one side to 45° on the other side of the plane of vibration of the polariser; or if the crystal be changed for another of an opposite character (*i.e.* negative for positive, or *vice versâ*), the quadrants which were first contracted will be expanded, and those which were first expanded will be contracted. Hence for a given position of the quarter-undulation plate the appearance of the rings will furnish a means of determining the character of the crystal under examination.

Similar effects are produced if the quarter-undulation plate be placed between the crystal and the analyser; that is, if the light be analysed circularly.

In the case of bi-axal crystals under the action of light polarised or analysed circularly, the black brushes are wanting, but they are replaced by lines of the same form marking where the segments of the lemniscatas pass from given colours into their complementaries.

If the light be both polarised and analysed circularly, all trace of direction will have disappeared. In uni-axal crystals the rings will take the form of perfect circles without break of any kind; and in bi-axal they will exhibit complete lemniscatas.

To pursue this matter one step farther. Suppose that, the arrangements remaining otherwise as before (viz., first, the polariser; secondly, a quarter-undulation plate with its axis at 45° to the principal plane of the polariser; thirdly, a uni-axal crystal; fourthly, a quarter-undulation plate with its axis parallel or perpendicular to the first; and, lastly, the analyser), the analyser be turned round; then in any position intermediate to 0° and 90° the rings will be contracted and extended in opposite quadrants until at 45° they are divided by two diagonals, on each side of which the colours are complementary. Beyond 45° the rings begin to coalesce, until at 90° the four quadrants coincide again. During this movement the centre has changed from bright to dark. If the motion of the analyser be reversed the quadrants which before contracted now expand, and *vice versâ*. Again, if the crystal be replaced by another of an opposite character, say positive for negative, the effect on the quadrants of the rings will be reversed. This method of examination, therefore, affords a test of the character of a crystal.

A similar process applies to bi-axal crystals; but in this case the diagonals interrupting the rings are replaced by a pair of rectangular hyperbolas, on either side of which the rings expand or contract, and the effect is reversed by reversing the motion of the analyser, or by replacing a positive by a negative crystal. The test experiment may then be made by turning the analyser slightly to the right or left, and observing whether the rings appear to advance to, or recede from, one another in the centre of the field. In particular if, the polariser and analyser being parallel, the first plate have its axis in a N.E. direction to a person looking through the analyser, the second plate with its axis at right angles to the former, and the crystal be so placed that the line joining the optic axes by N.S., then on turning the analyser to the right, the rings will advance towards one another if the crystal be negative, and recede if it be positive.

W. SPOTTISWOODE

(*To be continued.*)

FLOWERS OF THE PRIMROSE DESTROYED BY BIRDS

WE have received a number of answers to Mr. Darwin's letter on this subject in NATURE, vol. ix., p. 482; these we have thought it advisable to bring together here. On the general question of the destruction of flowers by birds, Prof. Thiselton Dyer writes as follows :—

MR. DARWIN remarks that he has never heard of any bird in Europe feeding on nectar. There is perhaps one well-authenticated instance in Gilbert White's "Selborne" (illustrated edition, p. 186): "The petticheps . . . . runs up the stems of the crown imperials, and putting its head into the bells of those flowers, sips the liquor which stands in the nectarine of each petal." This is the more curious, because, according to Kirby and Spence ("Entomology," 7th edition, p. 384), this plant "tempts in vain the passing bee probably aware of some noxious quality that it possesses." I do not know how far this is true, but it has a peculiar odour which makes it rather unpopular as a garden plant.

I have, in my note-book, another instance, also from the *Liliaceæ*, of a plant visited for nectar in an extra-tropical country. Mrs. Barber relates that in South Africa "the long tubular flowers of the aloe are well supplied with nectar, and this provision affords during the winter season a continued store of food for our beautiful sun-birds," the numerous species of the genus *Nectarinia* (Journ. R. Hort. Soc., n.s., ii. 80).

Two other cases of the destruction of flowers by birds occur to me. I was assured this year that the flowers of the common crocus are persistently destroyed by sparrows, at least in the neighbourhood of Hammersmith. The base of the perianth tube, which is the usual seat of any secretion of nectar, is here beneath the surface of the ground; perhaps, however, the style and stigma are attractive to the birds. I did not investigate the matter at all closely, but my informant was an observant person, who I think would be likely to have satisfied himself that the sparrows really did the mischief, the effects of which were obvious enough. If so, we have a clear instance in crocus-eating of an acquired habit on their part.

The other case, that of the destruction of flower-buds of fruit-trees by bullfinches, is probably well known. The mischief is said to be out of all proportion to any benefit the birds can derive from it, as regards food. Such a visitation would obviously tell heavily against the plants in any country where they formed part of the indigenous flora, and had to take their chance with the rest.

Dr. J. H. Gladstone writes, that in his garden the flowers of the primroses have been similarly bitten off, and the crocuses also. He says—

ONE morning some weeks ago I especially remember seeing the beds and the gravel walks strewn with the yellow petals of the latter flower, which were severed from their stalks, and bore abundant marks of the sharp beaks which had torn them asunder. I cannot learn that anyone saw these London birds at their destructive work, which was probably done before any of us were stirring.

Mr. T. R. Archer Briggs, of Plymouth, writes—

I HAVE been familiar with the fact to which Mr. Darwin directs attention for as long a period as that during which he says it has engaged his own, without, however, my being able to point out the author of the mischief. In the neighbourhood of Plymouth it is no uncommon thing to find the flowers both of the primrose and polyanthus bitten off and lying around the plants exactly as Mr. Darwin has described; indeed, so often does this occur here, that I have known it a source of annoyance to cultivators of the latter plant. When residing some years ago at a house in the parish of Egg Buckland, about four miles from Plymouth, I remember to have repeatedly seen the polyanthus flowers in the grounds so destroyed, and to have heard it asserted that the redbreast was the culprit; but of this no proof was brought forward. The locality is a land of springs and streams, and it could not have been a want of water that led the destroyer to do the work there.

The tubular portion of the primrose is much infested by small insects (*thrips?*), and I have sometimes thought that a bird, for the sake of feeding on these, might be led to bite the flowers; but, on the other hand, they are so minute that one can scarcely think they would attract its notice.

I would say, in reply to Mr. Darwin's queries, that primroses are in profusion about Plymouth (at least beyond the immediate neighbourhood of the town, whence they have been rooted out by wretched fern- and wild flower-grubbers), but I have never seen the flowers bitten off to such an extent as in the small Kentish wood he refers to, or in a sufficiently large quantity to materially affect the numbers of the species here.

The Rev. H. C. Key, of Stretton Rectory, Hertford, says that primroses being in great abundance in his neighbourhood, he was led by Mr. Darwin's letter to make a careful search for flowers bittten off in the way he describes, but he failed to find even one.

IT is obvious that the abundance of other food for which birds have a preference—such as apple, pear, plum, and cherry blossoms afford—may possibly have saved our primrose flowers from destruction; but, taking into consideration the fact that animal food must necessarily be supplied to the young birds at this season, I should be disposed to suggest that the primroses Mr. Darwin speaks of have been mutilated by birds rather for the sake of procuring thrips and other beetles, which are attracted by the nectar, than for the nectar itself.

I find the untouched primrose flowers here swarm with beetles and acari; but the great profusion of apple, and pear-blossom, &c., close at hand, may prove more attractive to the birds from the flowers being more open, and therefore more easily accessible.

Mr. G. M. Seabroke writes—

I HAVE observed the same thing as he relates in my small garden in this town. Nearly all the early buds from some twenty primrose plants were bitten off, and birds of some sort were undoubtedly the perpetrators of the mischief. I laid the blame on the sparrows, but did not see them in the act. This is the first year that I have noticed this form of depredation.

Mr. T. R. Stebbing, of Torquay, writes as follows :—

A FORTNIGHT ago the bank on either side of the road from Kingsbridge Road Station to Salcombe were covered, for many miles, with a brilliant profusion of primroses in bloom. In all this long range of country, eighteen miles in all, there was no appearance anywhere of that destruction of blossoms as to which Mr. Darwin makes inquiry. The attention of my companion and myself was especially directed to the primroses throughout our route, not merely by the lavish and unexpected beauty of the display, but by the look-out which we were keeping up for white or red varieties. Among the myriads of plants with the ordinary yellow blossom we noted five with white and two with pinkish flowers. On returning over a portion of the same road ten days later, we detected as many as seven plants with the pale-red or pink flowers, but none of these were blooming freely like the white and the yellow flowering-plants in the same district.

It may be worth noticing that this great stream of primroses flowed down from the rather bleak upland near the railway right into the fertile and sheltered valley of Salcombe, so that in one district or the other the birds might have been expected to seek the nectar, had they been to the manner born, in this part of the country.

A correspondent, E. T. S., says that—

IN the north-west corner of Hampshire the birds have the same taste as in Kent for the nectar of primroses and polyanthuses. A few weeks ago a correspondent wrote thence that this spring the blackbirds "were as bad as peacocks," whose well-known habit of cutting off the blossoms of polyanthuses, carnations, lilies, and any particularly choice tropical plant that they can get hold of, makes them a gardener's despair. A peacock who resided for a short time in the neighbourhood referred to, might possibly have taught the native birds the trick, but this is hardly probable, as he died three winters ago, and the present year, when all spring flowers have bloomed earlier and more abundantly than usual, is the first in which his example has been extensively followed. I should doubt the practice being limited to a single species. Sparrows certainly gather flowers very carefully; I have seen them almost strip a bed of the variegated arabis, though in this case the flower-stalks were carried away and used, not for food, but in nest-building. Does any other bird use fresh flowers for that purpose?

JOHN PHILLIPS

BORN DECEMBER 25, 1800: DIED APRIL 24, 1874

THE daily press has already spread the sad tidings from Oxford that Prof. Phillip met with an accident which suddenly cut short his life while in good health and such full vigour that we still expected work from him. A few days ago he was here amongst us in London, bearing himself with form as erect and step as elastic as if the last ten years had but further mellowed though in no way lessened his energy. Now we learn that a stumble over a door-mat, on leaving a friend's rooms in All Souls, followed by a heavy fall, has deprived Oxford of one of her brightest ornaments, and men of science of a genial friend.

Another bond is broken which linked together by a living presence the geologists of to-day with those who watched the infancy of the science which, in place of wild phantasies of the imagination as to the origin of our planet, substituted a patient and careful investigation of its structure, as far as observation was possible. From the time when William Smith in 1792-3 surveyed the ground between High Littleton and Bath for the Somersetshire Coal Canal, and proved an unvarying sequence in the strata of England, and their identification by their fossil contents, every "cosmogomy" and "theory of the earth" was doomed. Fact henceforth took the place of fancy.

Among the earliest of those trained in the new school was young John Phillips. Born at Marden, in Wiltshire, on Christmas-day (N.S.) 1800, he lost his father when he was but seven years old, and his mother dying soon after, his training fell into the hands of his mother's brother, the renowned William Smith, "Father of English Geology."

We have never heard that there was anything to be recorded of his father beyond that he was the youngest son in a Welsh family, settled for many generations on their own property at Blaen-y-ddol, in Caermarthenshire, who was destined for the Church, but became an officer of the Excise, and that he married the sister of William Smith. Mr. F. Galton, a few weeks ago, read a paper at the Royal Institution, in which he gave statistics about eminent scientific men, showing the number of cases in which the greatness was due to the father, and the number of cases in which it was due to the mother. Whether Prof. Phillips was included we do not know, but he most certainly was an instance in which the influence of the mother preponderated. The mould of the features were distinctly those of the Smith family, and the likeness between Prof. Phillips and the busts and pictures of William Smith has often been remarked. His habit of thought was so much due to the direct training of his uncle that we cannot trace how much of it was hereditary. No particular school could have much influenced him, for he passed through four schools before he was ten, and then for a short time went to the excellent old school at Holt Spa, in Wiltshire. It is said that Latin, French, and Mathematics were his favourite studies, and the enjoyment of Latin authors seems to have grown on him, for in the writings of no other geologist will be found so many quotations from the Latin classics. The Rev. Benjamin Richardson, Rector of Farley Hungerford, near Bath, was one of his earliest instructors in natural history. Very little, indeed, is known of Mr. Richardson; he had the reputation of being in his time the best naturalist in the west of England, and the obituary notices at the time of his death mention that he was a member of Christ Church, Oxford. One fact about him which has an historical interest is certain, and that is that it was his hand which, from the dictation of William Smith, "first reduced to writing at the house of the Rev. Joseph Townsend, Pulteney Street, Bath, 1799" the table of "the order of the strata and their imbedded organic remains in the vicinity of Bath." The original document is in the keeping of the Geological Society, and is regarded as a memorial of the first step towards the examination of strata on a definite plan, the first step in the science of geology as contrasted with cosmogony. During the year that young Phillips spent at the pleasant rectory of Farley, he heard continually of the importance attached to the discoveries of his uncle and of the results which, in the estimation of Richardson and Townsend, were to flow from it. Under Mr. Richardson's direction he spent a large portion of his time in searching for fossils through the valleys around Farley, and in making drawings of the fossils he found and of the recent forms that were most nearly allied to them in Mr. Richardson's extensive collections. Prof. Phillips always spoke with pleasure of his recollections of Mr. Richardson, and attributed to him both his early taste for natural history and the ready use of his pencil, which so often not only reproduced faithfully a geological section but artistically included the foliage and background recording the pleasant accompaniments of the work which principally engaged his attention. Mr. Richardson though a kind was not a flattering guide to the young man, for a frequent remark on being shown the drawing of a fossil was, "Very good John, now put that in the fire and try and do even better."

At the end of the happy year at Farley, young Phillips went to live with his uncle in London, to share with him his labour, his hopes, and his disappointments. William Smith had then just removed to Buckingham Street, after the fire in Craven Street, which had so disarranged his work. Here, however, he rearranged his collection of fossils, the first collection in which fossils were placed in their stratigraphical sequence. Made first at Cottage Crescent, Bath, removed to Trim Street, then to Craven Street, and Buckingham Street, this historical collection finally found a resting-place in the British Museum. Each separate stratum recognised by Smith had one or more shelves sloping to represent the dip as he knew them in the typical ground of the Dunkerton Valley, near Bath, where he first studied them. This was the collection from which young Phillips first derived his ideas of a geological museum for teaching purposes, and which he saw so often referred to by his uncle in explaining to his many visitors his new ideas, when urging upon them the national importance of his iscovery as regarded agriculture and mining. William Smith was then working at his map of England, and to this his best energies were given and all his money devoted. In the "Memoirs" of his uncle, published in 1844, Prof. Phillips has described all the delays and trials that attended the production of this, the first geological map of England ever produced. The indomitable courage shown by Mr. Smith in the face of every discouragement could not fail to impress young Phillips with the importance of his uncle's work, and to win respect for him. How he was attached to him, and how he valued his teaching, is apparent in many places in his writings. In the preface to the "Memoirs" he speaks of himself as "an orphan who benefited by his goodness, a pupil who was trained up under his care." The map was issued in 1815, and Mr. Smith's professional engagements rapidly increased, requiring him to visit all parts of the county. He conceived the plan of producing county geological maps on a scale considerably larger than that of the map of England, and on almost every journey his nephew was his glad companion, "haud passibus æquis;" and according to an established custom on all such tours, was employed in sketching parts of the road and recording on maps the geological features of the country. In 1821, the map of Yorkshire, in four sheets, was published, which were prepared and coloured by his own hands. Throughout the "Memoirs" we have indications of the way in which he worked under his uncle's direction. Here is one which

gives an insight into the way in which he gained his intimate knowledge of the strata of the country. "The whole of the remainder of 1821 was devoted to long and laborious wanderings. Two lines of operation were drawn through the country which required to be surveyed. On one of these Mr. Smith moved with the due deliberation of a commander-in-chief; the other was traversed by his more active subaltern, who afterwards found the means to cross from his own parallel to report progress at head-quarters." In this way 2,000 miles were traversed in six months, and he thus learned to rely on his own judgment. His work delighted him. "Innumerable rambles," he says, "led up every glen and across every hill, now sketching waterfalls, anon tracing the boundaries of rocks or marking the direction of diluvial detritus." As greater accuracy in tracing the boundary of different strata was thus acquired, the successive issues of the map of England were modified. The lines of these alterations were mostly traced by Mr. Phillips himself, and thus it was that differences appeared in maps which apparently belonged to the same "edition."

At length, in 1824, Mr. Smith was asked to deliver a course of lectures on his geological work at the newly-formed Yorkshire Philosophical Society. For this "new maps were coloured, new sections drawn, and even the distant cabinet of Mr. Richardson at Farley was laid under contribution, to supply illustrations for these discourses." Lectures at Hull, Scarborough, and Sheffield soon followed. The share that Mr. Phillips took in the preparation of these lectures brought him under the notice of the executive of the Yorkshire Philosophical Society; he was offered the curatorship of the new museum, and accepted it. This was one of the important events of his life. His work no longer came before the public in his uncle's name, he had an individuality of his own, "and commenced to make his own reputation." I was delighted to find in the prosecution of this duty innumerable proofs of the truth of Mr. Smith's views respecting the distribution of organic fossils, and saw very clearly that many of the strata in the north-eastern part of Yorkshire might be confidently identified with well-known formations in the south of England. Soon after (in 1826) he read before the Society the first paper he wrote. His subject was: The Direction of the Diluvial Currents of Yorkshire, and it was thought worthy of being reprinted in the "Philosophical Magazine." From this time his pen was ever active. His early geological papers were on Yorkshire, and with that county his name is indissolubly connected. In addition to the curatorship of the museum he was appointed one of the secretaries of the Society, and delivered courses of lectures, and in 1829 he published his illustrations of the Geology of Yorkshire.

It was not till 1834 that Mr. Phillips communicated a paper to the Geological Society, and in the same year he published his "Guide to Geology," was appointed Professor of Geology in King's College, London, and was elected a Fellow of the Royal Society. His recommendature to election into the Society is of sufficient interest to be printed, and is as follows:—

"John Phillips, Esq., of York, Fellow of the Geological Society of London and Secretary of the Yorkshire Philosophical Society, a gentleman well versed in geology, meteorology, and various branches of natural science, and author of "Illustrations of the Geology of Yorkshire," being desirous of becoming a Fellow of the Royal Society, we whose names are hereunto subscribed do, from our personal knowledge, recommend him, as highly deserving of the honour he solicits, and likely to prove a valuable and useful member.

"Rod. I. Murchison, Wm. Buckland, G. B. Gresnough, William Clift, Edw. Turner, Adam Sedgwick, John Taylor, H. T. De la Beche, C. Daubeny, John Edw. Gray, Geo. Peacock, John Lindley, B. Powell.

"Elected April 10, 1834."

Not only was he associated in work with the "father" of Geological Science, from which such valuable practical results have flowed, but he was one of the band who, in his own words, "stood anxious but hopeful by the cradle of the British Association." It is well known how through his activity the first meeting at York was a success in September 1831, and how till 1863 he was the courteous assistant-secretary of the Society.

Among other posts Prof. Phillips has filled are the Chair of Geology at Dublin, to which he was appointed in 1844; the Presidency of the Geological Society in 1859-60; Rede Lecturer in Cambridge in 1860; and the Presidency of the British Association in 1866. The Chair at Oxford he has held since 1853.

He not only helped to lay the foundations of English Geology, he has been to the last an active worker and an industrious writer. Besides more than sixty papers communicated to Societies' proceedings and to magazines, he was largely a contributor to the "Penny Encyclopædia," the "Encyclopædia Britannica," and the "Encyclopædia Metropolitana."

In 1841 was published his "Palæozoic Fossils of Cornwall, Devon, and West Somerset, after he had examined the country in company with Mr. William Sandars.

In 1842 he began an examination of the Malvern district, and having settled his data at Malvern, Abberley, and Woolhope, he extended his observations to May Hill, Fortworth, and Usk. The work was given to the world in 1848 as one of the Memoirs of the Geological Survey. "The Rivers, Mountains, and Sea-coast of Yorkshire" appeared in 1853, and his Essay in the "Oxford Essays," in 1855.

His contribution to the Palæontographical Society on the Belemnitidæ, and his "Geology of the Thames Valley," are well known; and he has also written many smaller works which we have not space to notice.

For many years he has been Keeper of the Museum at Oxford, and his lectures have had such a reputation for being popular that they have been largely attended by ladies. The Professor had also given much time to meteorology and astronomy, and had made many observations in his own observatory. He was an honorary M.A. and D.C.L. of Oxford, and LL.D. of Cambridge and Dublin.

NOTES

Dr. Lyon Playfair, C.B., has given notice that, on the House of Commons going into committee on the Education Estimates, he will call attention to the deficient ministerial responsibility under which the Votes for Education, Science, and Art are administered, and will move for a Select Committee to consider how such ministerial responsibility may be better secured. We believe that Dr. Lyon Playfair's views are strictly in accordance with those of the best scientific men of the country, namely, that the only satisfactory way of dealing with the subject will be by the appointment of a Minister for Education, Science, and Art.

The 15th or 16th of June has been fixed for the inauguration of the physical laboratory, the gift of the Duke of Devonshire to the University of Cambridge.

The following is a list of candidates selected and recommended by the Council of the Royal Society for election as Fellows:—Isaac Lothian Bell, F.C.S.; W. T. Blanford, F.G.S.; Henry Bowman Brady, F.L.S.; Dr. Thomas Lauder Brunton, Sc.D.; Prof. W. Kingdon Clifford, M.A.; Augustus Wollaston Franks, MA.; Prof. Olaus Henrici, Ph.D.; Prescott G. Hewett, F.R.C.S.; John Eliot Howard, F.L.S.; Sir Henry Sumner Maine, LL.D.; Edmund James Mills, D.Sc.; Rev. Stephen Joseph Perry, F.R.A.S.; Dr. Henry Wyldbore Rumsey; Alfred R. C. Selwyn, F.G.S.; Major Charles William Wilson, R.E.

It is stated that Dr. J. H. Gladstone, F.R.S., has been nominated to succeed Dr. Odling at the Royal Institution.

The funeral of the late Professor Phillips will be solemnised at York to-day at 11 A.M. It is understood that this locality was fixed on by himself, other members of his family being buried there.

A deputation, consisting of Sir Bartle Frere, president of the Royal Geographical Society, Sir James Watson, Lord Provost of Glasgow, Sir William Stirling Maxwell, M.P., and several other members of Parliament, waited on Lord Derby last Friday, to lay before him the claims which exist for an official recognition of the late Dr. Livingstone's arduous services in the cause of humanity and of Science during his long tenure of office as one of Her Majesty's Consuls. The memorial, which was handed to Lord Derby, was signed by many eminent and well-known names, and his lordship said he agreed with the deputation that something ought to be done for the members of Livingstone's family. There seems no doubt that Government will meet the wishes of the country in this matter.

On Monday night, at the usual meeting of the Royal Geographical Society, the principal business of the evening consisted of reading extracts from the letters of Dr. Livingstone to Sir H. Rawlinson, to Sir R. I. Murchison, to Sir Bartle Frere, and to some private friends. This correspondence extended over six or seven years. Very voluminous materials have been preserved, but the work of editing them has yet to be performed. Sir Bartle Frere was happy to say that the son of the illustrious traveller accepted the duty of editing the materials left by his father, and had resigned a promising career in Egypt for that purpose.

The *Spectator* proposes that as an appropriate memorial to the late Dr. Livingstone, some Exploration Scholarships should be founded, to be called by the explorer's name.

Mr. F. J. Schuster has made a donation of 225*l.* to the Physical Laboratory of Owens College, Manchester, for the purpose of buying apparatus.

The Royal Irish Academy has sanctioned the following grants from the fund at its disposal for aiding scientific researches by providing suitable instruments and materials :—30*l.* to Messrs. Studdert and Caldwell for the chemical analysis of the mineral waters at Lisdoonvarna, in the county of Clare; 30*l.* to Prof. Macalister, to be expended in the purchase of rare insectivora and other mammals for dissection, in order to enable him to report on the myology of mammals; 40*l.* to Mr. W. H. Bailey, to investigate the fossils of the coal districts in Ireland, with a view to their comparison with those of British and other coal-fields; 50*l.* to Prof. Haughton, to complete an investigation into the chemical and mineral composition of the successive lava-flows of Vesuvius; 39*l.* 17*s.* 11*d.* (being the remainder of the fund) to Dr. David Moore, for the investigation and cataloguing of the Irish Hepaticæ. Gentlemen purposing to undertake scientific researches during the coming year, and desirous to obtain grants from this fund, are invited to send in their applications to the secretary of the Academy without delay.

The Ogham inscribed stones, ten in number, purchased by the Royal Irish Academy from the representatives of the late Mr. Windele, have been arranged in the crypt of their Museum with the other Ogham stones belonging to the Academy, one being set vertically in the floor, and the others placed either on iron stands in the bays at the south side, or on the dwarf walls forming the bays. These stones are now all easy of access, and, in the daytime, have the advantage of a light well adapted to the examination of their respective inscriptions. The Academy is in possession of 134 photographic negatives of Ogham inscriptions, representing about eighty different texts. It is intended to print these in autotype, and thus to afford to inquirers in this curious branch of study authentic copies of considerably more than half the whole number of such inscriptions known to exist. They will be accompanied by short notices, strictly limited to a statement respecting the localities where the inscriptions were found, and other matters of fact respecting them; the philological discussion and interpretation of them being left to the free competition of scholars.

Rear-Admiral Charles H. Davis was ordered, on Feb. 23, to the duty of superintendent of the Naval Observatory at Washington, U.S., in place of Rear-Admiral Sands, who has been detached and placed on the retired list, in accordance with the rules of the service. Admiral Sands, during his tenure of office, has merited the respect and goodwill of British Astronomers, who will view with regret the necessary termination of his functions.

Amongst the estimates passed by the House of Commons on Friday last was 80,000*l.* to continue the works on the New Natural History Museum at South Kensington, with which rapid progress is now being made.

In answer to a question in the House of Commons on Tuesday Viscount Sandon stated that arrangements consequent on the retirement of Mr. Cole were now the subject of consideration by the Science and Art Department, but had not yet been completed.

The Council of the Paris Observatory is said to have protested against a ministerial decision which allowed the Bureau des Longitudes to take the half of the astronomical library, which has been forming during centuries, and which is one of the richest in the world. It is almost certain that the decision will be cancelled, M. Leverrier having given the alternative of leaving the whole of the books in the hands of the Bureau, and refusing to be a party to such a mutilation. When the library shall be saved, it will be open to the public under certain regulations.

We recently announced the oppressive treatment to which M. Alglave, editor of *La Revue Scientifique* and Professor of Law at Douai, had been subjected; there is no doubt now that his suspension by the Minister of Public Instruction has been caused by his refusal to resign the editorship of the journal just mentioned and of the *Revue politique et littéraire*, of which he is also editor. On Monday week, on his going to open his class for the term, he received a letter from the Under-Secretary of the Education Department informing him that his course would be suspended until further notice. Science has many difficulties to contend with in this country, but happily vexatious interference on the part of the State is not one of them.

A paper on the grasses and fodder plants which may be beneficial to the squatter and agriculturist in South Australia, by Dr. Richard Schomburgk, director of the Adelaide Botanic Gardens, has been officially published by order of the Governor.

It is stated in the *Scientific American* that the well-known and much admired Japan lacquer-work, the secrets of which were supposed to be known only to the Easterns, has been successfully reproduced, or rather imitated, in Holland. The lacquer is prepared from Zanzibar copal, coloured black with Indian ink. The articles are painted with several coats of this lacquer, in which the pieces of mother-o'-pearl or other substances used for ornamentation are placed before it becomes hard. The lacquer is then dried by placing the articles in a heated oven or furnace, after which another coat of lacquer is applied, and when dry smoothed with pumice, which is repeated until all cracks are filled up and the surface has become perfectly smooth, when the whole is polished, or rather burnished, with tripoli.

THE Russian Scientific Expedition to the Amu Daria was to set out on Monday last. The expedition will be commanded by the Grand Duke Nicholas Constantinovitch, assisted by Colonel Stoletoff and Dr. Moreff, secretary. It will include 25 persons, whose work will be divided into four sections :—(1) The Trigonometrical and Topographical. (2) The Meteorological Section, which will construct two stations on the Amu Daria, at one of which hourly observations will be made of all the meteorological phenomena. (3) The Ethnographical Statistical Section. (4) The Natural History Section.

THE meeting of French Astronomers took place last week at the Ministry of Public Instruction, under the presidency of M. Leverrier. It was composed of M. Dumeril, director of the *Enseignement*, the astronomers from Paris, Toulouse, and Marseilles Observatories, and Officers from the General Staff of the Trigonometrical Survey. Four sittings were held, and an account of them will be issued shortly. Steps have been taken for the determination of the latitude of Algiers, by telegraph. M. du Barail, Minister of War, and M. Saget, his Staff-Officer, visited the Observatory last Saturday, in order to see for themselves how the work may be begun without further delay.

THE additions to the Zoological Society's Gardens during the last week include four Bladder-nosed Seals (*Cystophora cristata*) from Greenland, presented by Capt. Alex. Gray; a White-winged Whydah Bird (*Urobrachya albonotus*) from West Africa, presented by Mr. J. Fairchild; a Rose-crested Cockatoo (*Cacatua moluccensis*) from the Moluccas, presented by Mr. H. Baldwin; an Azara's Fox (*Canis azaræ*) from South America; a Snowy Owl (*Nyctea nivea*) from South America; a Green-cheeked Amazon (*Chrysotis viridigenalis*) from Columbia, purchased.

ON THE REFRACTION OF SOUND*

THE principal object of this paper is to show that sound, instead of proceeding along the ground, is lifted or refracted upwards by the atmosphere in direct proportion to the upward diminution of the temperature; and hence to explain several phenomena of sound, and particularly the results of Prof. Tyndall's recent observations off the South Foreland.

The paper commences with the explanation of the effect of wind upon sound, viz., that this effect is due to the lifting of the sound from the ground, and not to its destruction, as is generally supposed. The lifting of the sound is shown to be due to the different velocities with which the air moves at the ground and at an elevation above it. Owing to friction and obstructions the air moves slower below than above, therefore sound moving against the wind moves faster below than above, and the bottom of the sound waves will thus get in advance of the upper part, and the effect of this will be to refract or turn the sound upwards; so that the rays of sound which would otherwise move horizontally along the ground actually move upwards in circular or more hyperbolic paths, and may thus, if there is sufficient distance, pass over the observer's head. This explanation was propounded by Prof. Stokes in 1857, but it was discovered independently by the author.

The paper then contains descriptions of experiments made with a view to establish this explanation.

These experiments were made with an electric ball, over a nearly flat meadow, and again over the same when it was nearly covered with snow, and it was found (as indeed it was expected) that the condition of the surface very materially modified the results in two ways. In the first place, a smooth surface like snow obstructs the wind less than grass, hence over snow the wind has less effect in lifting the sound moving against it than over grass; and it is inferred that a still greater difference would be found to exist in the case of smooth water. In the second place, the ends of the waves of sound travelling along in contact with the rough ground are continually destroyed by the roughness, and the sound from above slowly diverges down to replace that which is destroyed, and this divergence gradually weakens the intensity of the lower parts of the waves, so that, under ordinary circumstances, the sounds which pass above us are more intense than those we hear. The general conclusions drawn from these experiments are :—

1. The velocity of wind over grass differs by ½ at elevations of 1 and 8 feet, and by somewhat less over snow.

2. That when there is no wind, sound proceeding over a rough surface is destroyed at that surface, and is thus less intense below than above; owing to this cause the same sound would be heard at more than double the distance over snow at which it could be heard over grass.

3. That sounds proceeding *with* the wind are brought down to the ground in such a manner as to counterbalance the effect of the rough surface (2), and hence, contrary to the experiments of Delaroche, the range of sound over rough ground is greater with the wind than at right angles to its direction or than when there is no wind. When the wind is very strong it would bring the sound down too fast in its own direction, and then the sound would be heard farthest in some direction inclined to that of the wind though not at right angles.

4. That sounds proceeding against the wind are lifted off the ground, and hence the range is diminished at low elevations. But that the sound is not destroyed and may be heard from positions sufficiently high (or if the source of sound be raised) with even greater distinctness than at the same distances with the wind.

5. In all cases where the sound was lifted there was evidence of diverging rays. Thus although on one occasion the full intensity was lost when standing up at 40 yards the sound could be faintly and discontinuously heard up to 70 yards. And on raising the head the sound did not at once strike the ear with its full intensity nor yet increase quite gradually; but by a series of steps and fluctuations in which the different notes of sound were variously represented, showing that the diverging sound proceeds in rays separated by rays of interference.

On one occasion it was found that with the wind sound could be heard at 360 yards from the bell at all elevations, whereas at right angles it could be only heard for 200 yards standing up, and not so far at the ground; and against the wind it was lost at 30 yards at the ground, at 70 yards standing up, and 160 yards at an elevation of 30 feet, although it could be distinctly heard at this latter point from a few feet higher.

It hence appears that these results agree so well with what might be expected from the theory as to place its truth and completeness beyond question.

The author then goes on to argue from the action of wind upon sound to another phenomenon which admits of a somewhat similar explanation. The effect of wind together with that of a rough surface in lifting the sound may be shown to account for many of the apparently capricious variations in the intensity with which sounds can be heard at different times; and it gives a reason for the custom which prevails of elevating church bells, platforms, &c., where the sounds are intended to be heard at a distance. But it does not explain a fact, which has often been observed, namely, that distant sounds can be heard much better during the night than during the day, and on dull cloudy days better than on bright hot days. This phenomena has engaged the attention of Humboldt, Delaroche, and recently of Prof. Tyndall, who have all assumed that the sound is obstructed or destroyed in the bright hot air, and have suggested causes which they thought might produce this effect. These suggestions are all more or less open to objection, and none of them meet the difficulty that any heterogeneous condition of the air which could obstruct sound must more or less refract or reflect light and so render vision indistinct. In this paper the author gives another explanation, in which he shows how, as in the case of wind, the sound may be lifted and not destroyed.

It is argued that since wind raised the sound simply by causing it to move faster below than above, any other cause which produces such a difference in velocity will lift the sound in the same way. And since the velocity of sound through air increases with the temperature—every degree from 32 to 70 adding 1 foot per second to the velocity—therefore an upward diminution in the temperature of the air must produce a similar effect to that of wind and lift the sound. Whereas Mr. Glaisher has shown by his balloon observations that such a diminution of temperature exists, and further he has shown that when the sun is shining with a clear sky the variation from the surface is 1° for every

* On the Refraction of Sound by the Atmosphere. By Prof. Osborne Reynolds, Owens College, Manchester. Abstract of paper read before the Royal Society April 23.—Communicated by the Author.

100 ft., and that with a cloudy sky it is only half what it is with a clear sky. These results were from the mean of his observations; under exceptional circumstances the variations were both greater and less. It is hence shown that rays of sound otherwise horizontal would be bent upwards in the form of circles, the radii of which with a clear sky are 110,000 ft., and with a cloudy sky 220,000 ft., so that the refraction is double as great on bright hot days as it is when the sky is cloudy, and still more under exceptional circumstances, and comparing day with night.

It is then shown by calculation that the greatest refraction—110,000 ft. radius—is sufficient to render sound from a cliff 235 ft. high inaudible on a ship's deck 20 ft. high at $1\frac{3}{4}$ miles, except such sound as might reach the observer by divergence from the waves above, whereas when the refraction is least—220,000 ft. radius—or where the sky is cloudy, the range would be extended at $2\frac{1}{2}$ miles with a similar extension for the diverging waves. It is hence inferred that the phenomenon which Prof. Tyndall observed on July 3, and other days—namely that when the air was still and the sun was hot he could not hear guns and sounds from the cliffs of South Foreland, 235 ft. high, for more than two miles, whereas when the sky clouded, the range immediately extended to three miles, and as evening approached much farther,—was due, not so much to stoppage or to reflection of the sound by invisible vapour as Prof. Tyndall has supposed, but to the sounds being lifted over his head in the manner described; and that had he been able to ascend 30 ft. up the mast, he might at any time have extended the range of the sound by a quarter of a mile at least. Or had the instruments on the top of the cliff been compared with similar instruments at the bottom, a very marked difference would have been found in the distances at which they could be heard.

It seems that there were instruments at the bottom, and it is singular that throughout his report Prof. Tyndall makes no comment on their performance, unless they were at once found to be so inferior to those at the top that no further notice was taken of them; this seems possible, since beyond mentioning that they were there, Prof. Tyndall throughout his report never refers to them.

It also seems that besides those results of Prof. Tyndall's experiments, there are many other phenomena connected with sound, of which this refraction affords an explanation, such as the very great distances to which the sound of meteors has been heard as well as the distinctness of distant thunder. When near, guns make a louder and more distinctive sound than thunder, although thunder is usually heard to much greater distances. In hilly countries, or under exceptional circumstances, sounds are sometimes heard at surprising distances. When the Naval Review was at Portsmouth, the volleys of artillery were very generally heard in Suffolk, a distance of 150 miles. The explanation being that owing to refraction (as well as to the other causes) it is only under exceptional circumstances that distant sounds originating low down are heard near the ground with anything like their full distinctness, and that any elevation either of the observer or of the source of sound above the intervening ground causes a corresponding increase in the distance at which the sound can be heard.

SCIENTIFIC SERIALS

Memorie della Societa degli Spectroscopisti Italiani, February.—Father Secchi contributes a paper On his Observations of Solar Prominences from April 23 to October 2, 1873. From his tables it appears that the sun was observed on 127 days, when 1,052 prominences were seen, being more than 8 a day, the maximum number visible on any one day was 13, and the minimum 2. The greatest number of prominences over 64″ high occurred in lat. 30° 40′ N. and 20° 30′ S. The greatest number of prominences of all kinds were in lat. 20° 30′ N. and 10° 20′ S. The same author also makes some remarks on the spectroscopic observations of the transit of Venus.

Astronomische Nachrichten, Nos. 1,980–1,981.—These numbers contain a large quantity of observations of positions of the minor planets and comets made in 1873 by Leopold Schulhof. He also gives the positions of more than 100 variable stars, with remarks on a new variable position for 1850, RA 23° 10′ 35″ Dec. − 19° 39″·7. Prof. Peters gives the position of Planet 135, Feb. 18, 1874, at 14h. 37m. 40s., Hamilton College, M.T., RA 11h. 19m. 42·7s. Dec. + 4° 25′ 5″·11 mag. G. Spoerer gives the positions of spots and prominences for February last. J. Palisa gives the position of the planet discovered by him on March 18, 4h. 46m. 39s. RA 12h. 22m. 2·12s. Dec. − 3° 19′ 33″·4.

No. 1,982 contains a long paper On a Method of Computing Absolute Perturbation, being in great measure similar to that of Laplace.

Journal of the Franklin Institute, March.—This number contains an account, by Mr. Crew, of the "prismoidal" one-rail railway (of his invention), of which he has made two years' trial in Alabama, with encouraging results. The cars are kept securely on the prismoidal track by a combination of wheels; a centre one, at either end, on the rail, kept on the track by revolving flanged wheels at either side; and wheels on the sides of the prismoid, with strong wrought-iron bars to the side of the car; these keep the car upright. One proposed application of the system is that of elevated rapid transit by steam through crowded streets in populous cities. As to speed, Mr. Crew thinks even 100 miles an hour would be possible; there is no oscillation through lateral motion.—Mr. Richards continues his Principles of Shop Manipulation for Engineering Apprentices; treating of belts, gearing, hydraulic and pneumatic apparatus as means of transmitting power, and of "machinery of application" of power.—Mr. Isherwood points out a method of ascertaining what portion of the feed-water admitted to a boiler is entrained in the form of spray by the escaping steam.—Details with reference to the Girard Avenue Bridge (which will form the chief entrance to the West Park, at Philadelphia), are furnished by Mr. Hering.—Prof. Thurston claims for Count Rumford a higher place in connection with thermo-dynamics than has hitherto been assigned to him; affirming that he first, and half a century before Joule, determined with almost perfect accuracy the mechanical equivalent of heat, while the sole credit of discovering the true nature of heat is due to him.—We may note, in addition, a paper On Railway Crossings and Turnouts, by Mr. Evans, and one On the Sanitary Care and Utilisation of Refuse in Cities, by Dr. Leas, who describes, more especially, the system followed in Baltimore.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 23.—On some points connected with the Circulation of the Blood, arrived at from a study of the Sphygmograph Trace, by A. H. Garrod, B.A., Fellow of St. John's College, Cambridge.

The author commences by giving a table containing a fresh series of measurements of the ratio borne by the cardiosystole * to its component beat in the cardiograph trace. These tend strongly to substantiate the law previously published by him, viz., that the length of the cardiosystole is constant for any given pulse-rate, and that varies as the square root of the length of the pulse-beat only, being found from the equation $xy = 20\sqrt{x}$ when $x =$ the pulse-rate and $y =$ the ratio borne by the cardiosystole to the whole beat.

A similar series of fresh measurements are given in proof of the law previously published by him, that in the sphygmograph trace from the radial artery at the wrist, the length of the sphygmosystole † is constant for any given pulse-rate, but varies as the cube-root of the length of the pulse-beat, it being found from the equation $xy' = 47\sqrt[3]{x}$, where $x =$ the pulse-rate, and $y' =$ the ratio borne by the sphygmosystole to the whole beat.

By measurement of sphygmograph tracings from the carotid in the neck and posterior tibial artery at the ankle, it is then shown that the length of the sphygmograph in those arteries is exactly *the same* as in the radial; so that the above-stated law as to the length of the sphygmosystole in the latter applies to them also, and must therefore equally apply to the pulse in the aorta.

Such being the case, by comparing the equations for finding the length of the cardiosystole with that for finding the aortic sphygmosystole, the relation between the whole cardiac systolic act and the time during which the aortic valve remains open can be estimated with facility; for by subtracting the shorter sphygmosystole from the longer cardiosystole a remainder is obtained which can be nothing else than the expression of the

* The *cardiosystole* is the interval between the commencement of the systole and the closure of the aortic valve in each revolution.

† The *sphygmosystole* is the interval between the opening and closure of the aortic valve in each cardiac revolution.

time occupied by the ventricle at the commencement of its systole in raising its internal pressure to that of the blood in the aorta, which must occur before the aortic valve can open up. This interval is named the *syspasis*. Its length is found to decrease ve y rapidly with increase in the pulse-rate, and to become *nil* at a pulse-rate of 170 a minute. An attempt is made to explain these phenomena.

If the above considerations are correct, certain independently obtained measurements ought on comparison to correspond; for by reference to one of the papers in the Society's Proceedings it is shown that the length of the there-termed second cardio-arterial interval (which may be called the second cardio-radial interval, as the artery under consideration was the radial), can only represent the time taken by the second or dicrotic wave of the pulse in travelling from the aortic valve to the wrist. This being so, there is every *à priori* reason in favour of the earlier primary wave taking the same time in going the same distance; which can be expressed in other terms by saying that the length of the first cardio-radial interval, from which that of the syspasis has been subtracted, ought to be exactly the same as that of the second cardio-radial interval. That such is the case is proved by the two measurements, which have been arrived at independently, agreeing in all cases *to three places of decimals*, which is great evidence in favour of the accuracy of the methods and arguments employed.

The latter part of the paper is occupied with the description of and the results obtained by the employment of a double-sphygmograph, by means of which simultaneous tracings are taken from two arteries at very different distances from the heart. The arteries experimented on are the radial at the wrist and the posterior tibial behind the ankle, 29 and $52\frac{1}{2}$ inches respectively from the aortic valves. From the resulting traces the time occupied by the pulse-wave in travelling the difference of distance—$(52.5 - 29) = 23.5$ inches is given—is found to be 0·0012 of a minute in a pulse of 75 a minute, and it is shown that this varies very little with difference in pulse-rate, as other considerations would lead us to expect; it is also proved that *there is a marked acceleration of the pulse-wave as it gets further from the heart.*

By superposing the simultaneous trace from the wrist on that from the ankle, direct verification is obtained of the earlier proposition, that the sphygmosystole at the wrist and at the ankle are of exactly similar duration. The peculiarities of the ankle trace are also referred to.

Geological Society, April 15.—John Evans, F.R.S., president, in the chair.—The following communications were read: About Polar Glaciation, by J. F. Campbell. The author commenced by referring to a reported statement of Prof. Agassiz, to the effect that he supposed the northern hemisphere to have been covered in glacial times from the pole to the equator by a solid cap of ice. He described his observations made during thirty-three years, and especially those of last summer, when he travelled from England past the North Cape to Archangel, and thence by land to the Caucasus, Crimea, Greece, and the south of Europe. His principal results were as follows:—In advancing southwards through Russia a range of low drift hills occurs about 60° N. lat., which may perhaps form part of a circular terminal moraine left by a retreating polar ice-cap; large grooved and polished stones of northern origin reach 55° N. lat. at Nijni Novgorod, but further east and south no such stones could be seen. The highest drift beds along the whole course of the Volga seem to have been arranged by water moving southwards. In America northern boulders are lost about 39°, in Germany about 55°, and in Eastern Russia about 56° N. lat., where the trains end and fine gravel and sand cover the solid rocks. Ice-action, in the form either of glaciers or of icebergs, is necessary to account for the transport of large stones over the plains, and the action of moving water to account for drift carried farther south. There are no indications of a continuous solid ice-cap flowing southward over plains in Europe and America to, or nearly to, the equator; but a great deal was to be found on shore to prove ancient ocean circulation of equatorial and polar currents, like those which now move in the Atlantic, and much to prove the former existence of very large local ice-systems in places where no glaciers now exist.—Note regarding the Occurrence of Jade in the Karakash Valley, on the southern borders of Turkestan, by Dr. Ferdinand Stoliczka, Naturalist attached to the Yarkund Mission. In this paper the author described the jade-mines on the right bank of the Karakash river formerly worked by the Chinese. There are about 120 holes in the side of the hill, and these at a little distance look like pigeon-holes. The rocks are a thin-bedded, rather sandy syenitic gneiss, mica- and hornblende-schists, traversed by veins of a white mineral, apparently zeolitic, which in turn are traversed by veins of jade.

Zoological Society, April 21.—Viscount Walden, F.R.S., president, in the chair.—The secretary read a report on the additions that had been made to the Society's Menagerie during the month of March 1874. Amongst these particular attention was called to a scarce Parrot (*Chrysotis finschi*), of which a specimen had been presented by Mrs. Chivers.—A communication was read from Mr. Morton Allport On the capture of a Grilse in the River Derwent, in Tasmania, showing that the salmon had really been successfully introduced into the colony.—Communications were read from Dr. J. E. Gray, F.R.S., On the very young of the Jaguar, *Felis* (*Leopardus*) *onca*; On the short-tailed Armadillo, *Muletia septemcincta*; On the young of the Bosch Vark, *Potamochœrus africanus*, from Madagascar; and On the Skulls of the Leopard in the British Museum.—A communication was read from Dr. O. Finsch, containing the description of a new species of Penguin, from New Zealand, which he proposed to call *Eudyptula albosignata*.—Mr. Edwin Ward exhibited the skull and horns of a fine specimen of the Persian Stag (*Cervus maral*) from the Crimea.—A communication was read from Capt. W. H. Unwin, containing an account of the breeding of the Golden Eagle (*Aquila chrysaetos*) in North-Western India.—Mr. J. E. Harting read a paper On a new species of *Tringa*, from St. Paul's Island, Alaska, which he proposed to name *Tringa gracilis*.—A communication was read from Lieut. R. Wardlaw Ramsay, giving the description of an apparently new species of Woodpecker, which he had obtained in a teak-forest, about six miles to the north of Tanghoo in British Burmah. Mr. Ramsay proposed to name it *Gecinus erythropygius*.—Messrs. W. T. Blanford and H. E. Dresser read a monograph of the genus *Saxicola*, Beechstein, being an attempt to reduce into some order the excessively confused nomenclature of the species composing this genus.

Royal Horticultural Society, April 15.—Scientific Committee.—M. T. Masters, M.D., F.R.S., in the chair.—Mr. Worthington Smith exhibited a drawing of a very curious fasciation in the aërial roots of *Aerides crispum*, in which the roots presented the curious flattened appearance so often met with in the branches of the ash, the shoots of asparagus, &c.—Mr. W. G. Smith also showed a drawing of the very rare *Angræcum ellisii*, from the collection of Mr. Day, of Tottenham. Mr. Smith remarked that the flowers turn brown when bruised.—Mr. Smith also showed a wood-engraving made on the wood of green ebony, *Brya ebenus*. Mr. Smith reported that for engraving purposes this was as good as bad box.—Prof. Thiselton Dyer showed dried specimens of a variety of *Hibiscus rosa-sinensis* from Zanzibar, where it was found wild by Dr. Kirk. The petals are palmately cut, as in *Clarkia*, *Schizopetalum*, &c. Dr. Masters made some remarks on the analogy the divided petals of this plant presented with the stamens of mallows, which it is now supposed consist of five primary organs, subsequently dividing into numerous anther-bearing filaments. It is doubtful whether *Hibiscus rosa-sinensis* has been heretofore observed in a truly wild condition. The discovery of the plant in east tropical Africa is therefore particularly interesting. It is possible, however, that it may prove a distinct species.—Prof. Thiselton Dyer also showed an elegant white fungus, having the appearance of lace, from Santarem. The Rev. M. J. Berkeley considered it probable that it was the fungus published by Kunze as *Rhizomorpha corynephora*.—Mr. Andrew Murray exhibited a fungoid production existing on trees over a considerable space in the Yosemite Valley, in California. Mr. Berkeley considered it near to the fungus called *Dothidea morbosa*, but there was also a gall on the same shoot.—Mr. Murray exhibited larvæ of a beetle closely allied to *Hammaticherus heros*, a beetle very destructive to timber in Germany, found feeding on the roots of fir near Enfield. Specimens of the perfect living insect have from time to time been found in the gun-stocks of walnut wood in the small-arms factory. It seems, therefore, a fair inference that the insects had escaped thence, and may perhaps have become naturalised—a most undesirable thing, for the larva is very destructive to timber. Mr. Blenkins remarked that he was familiar with the insect in the Crimea.

General Meeting.—H. Little in the chair.—The Rev. M. J. Berkeley commented on the plants exhibited. *Arthropodium cirrhatum* was an interesting plant of striking habit from New Zealand. When first introduced into this country, some years ago, it was supposed to have come from New Holland.

Physical Society, April 18.—Dr. Gladstone, F.R.S., in the chair.—Dr W. H. Stone read a paper On Wind Pressures in the human chest during performance on wind instruments. The author's object was to ascertain (1) what was the extreme height of a column of water which could be supported by the muscular act of expiration transmitted by the lips: this was found to be about 6 ft.; and (2) what was the actual pressure corresponding to the full production of a note on each of the principal wind instruments. It was found that with the majority of wind instruments the pressure required for the high notes is considerably greater than that required for the low notes, each instrument having a pressure-ratio of its own. The clarinet is an exception to the rule.—Mr. Tribe illustrated by experiments the action of hydrogen upon finely divided metals, such as are produced by precipitation.

Edinburgh

Royal Physical Society, April 22.—R. Scot Skirving, president, in the chair.—Recent Modes of determining the Impurity of Milk, by J. Falconer King, City Analyst. The only sure way to determine the quality of milk is to make a proper and careful chemical analysis of it.—Additional Note on the Suspension of Clay in Water, by Wm. Durham. Finely-powdered silica was found to behave in a manner generally similar to clay. Experiments seem to show that each solution has a specific capacity of sustaining clay, and also that this capacity varies in a specific manner according to the strength of the solution.—Note on the Formation of Boulder Clay, by D. J. Brown. Mr. Brown advocated that the usually accepted theory of the land origin of boulder clay would not explain the nature of this remarkable deposit, and considered that it was formed at the line of junction of the Arctic glacier with the sea.—On Fused Stones, showing Columnar Structure from a Pictish Tower, by the Rev. Jas. M. Joass, Golspie. These stones, in their columnar structure, illustrate, though on a small scale, an important geological phenomenon. The instance usually cited in illustration of the development of columnar structure in a melted mass is that of grain-tin, which forms rude columns on cooling. The author ventures to think that these fused stones afford a new and rather better illustration of the geological phenomenon, more closely analogous to the case of lavas, inasmuch as we have, in fact, a fused silicate, an artificial lava, forming columns the same in character as those of the Giant's Causeway, Samson's Ribs, or the pillars of Fingal's far-famed cave.

Paris

Academy of Sciences, April 20.—M. Bertrand in the chair.—The following communications were read:—Letter relating to a calculation, by Pouillet, on the cooling of the sun's mass, by M. Faye. The author showed that Pouillet's calculation tacitly implied that the sun's mass was not susceptible of contraction, and again restated his belief that solar radiation is not maintained by external causes, but is to be looked for in the formation of the sun itself, and in the enormity of its mass.—Observations concerning a communication, by M. Crocé Spinelli, on the lines of aqueous vapour in the solar spectrum, a letter from P. Secchi to the perpetual secretary. The author stated, that although the elements of water would be dissociated at the high temperature of the sun, their combination might take place in the ascending currents accompanying spots and eruptions owing to the lowering of temperature in these currents produced by expansion.—Tenth memoir on the formation of various crystalline substances in capillary spaces, by M. Becquerel.—New researches on the cyanogen series, by M. Berthelot. A continuation of this author's valuable researches in thermo-chemistry.—Heat of formation of the Cyanogen compounds, by M. Berthelot.—On Phylloxera and the American vines at Roquemaure (Gard), a note by M. J. E. Planchon.—Collimating level and its employment for foggy horizons, by M. G. M. Goulier.—On Orometric dials, specially applicable to pocket barometers, by the same author.—On partial differential equations which can be integrated without arbitrary functions, by M. de Pistoye.—On the "singular points" of algebraical plane curves, by Mr. Halphen.—On the rôle of salts in the action of potable waters on lead, by M. Fordos. The author recommended, as the results of his experiments, the filtration of all water issuing from lead conduits.—Mode of preservation of the wood employed in large manufactures and in railways, by M. Hubert. The preservative is hydrated ferric oxide.—On the absorption of oxygen and the emission of carbonic acid by leaves kept in darkness, by MM. P. P. Dehérain and H. Moissan. The authors have proved that leaves kept in the dark give off a quantity of CO_2 increasing with the temperature, that the quantity of CO_2 given off is comparable to that given off by cold-blooded animals, that the leaves absorb more oxygen than they give off CO_2, and that they continue to evolve CO_2 in an atmosphere deprived of oxygen.—Facts concerning the vibration of the air in sonorous pipes, by M. E. Gripon.—On a new thermo-electric pile, by M. C. C. Clamond.—On a volume regulator for gas currents, by M. H. Giroud.—On tetra-iodide of carbon, by M. G. Gustavson. This substance has been obtained by the action of tetrachloride of carbon upon dialuminic hexiodide, according to the equation $3CCl_4 + 2Al_2I_6 = 3CI_4 + 2Al_2Cl_6$; the two substances being dissolved in carbon disulphide. It was described as a red crystalline substance decomposed by heating in the air into CO_2 and free iodine.—New researches on black phosphorus, by M. Blondlot.—Action of pure hydrogen on silver nitrate, by M. H. Pellet. The author stated that a neutral or slightly acid solution of the salt is not reduced in the cold by pure hydrogen, and that an alkaline solution is reduced in the cold to an extent proportional to its alkalinity, elevation of temperature increasing the reducing action.—Researches on soluble phosphates used in agriculture, by M. A. Millot.—On the direct determination of the degree of intensity of explosive mixtures: application of the method to gunpowders, by M. Chabrier.—Action of bromine on dibromsuccinic acid; tribromsuccinic acid, by M. E. Bourgoin. The following substances are obtained by the action of bromine and water on the acid: tribromsuccinic and dibrom-maleic acids and dibrominated ethylene dibromide.—On the alcohols contained in the acid liquors of starch manufactories and in the products of the butyric fermentation of glucose, by M. G. Bouchardat. These are ethylic, normal propylic, and butylic alcohols.—On the determination of alcohol in water, wines and saccharine liquors, by M. Salleron.—General method for the transformation of alcohols into nitric ethers, by M. P. Champion. The reagent employed is nitro-sulphuric acid.—On phenyl-allyl, by M. B. Radziszewski.—On pyrogallol in presence of iron salts, by M. E. Jacquemin.—On the colouring matter of wine, by M. E. Duclaux.—On the volatile acids of wine, by the same author.—Movements excited in the stamens of *Mahonia* and *Berberis*; anatomical conditions of this movement, by M. E. Heckel.—On the direction of the wind in the high and low (atmospheric) regions during the storm of April 13, 1874, by M. Chapelas.—During the meeting a commission was appointed to prepare a list of candidates for the vacancy of foreign associate caused by the death of M. De la Rive.

LEWES'S "PROBLEMS OF LIFE AND MIND"

Problems of Life and Mind. By George Henry Lewes. First Series: The Foundation of a Creed. Vol. I. (Trübner & Co.)

IN this volume Mr. Lewes speaks in an attractive, if rather conversational way, on a great many philosophical and psychological topics; but the most striking feature of the book is the many announcements of discoveries and original views to be proved and elaborated in future volumes. And the author's opinion that the work is of "somewhat ambitious pretensions" is, we think, likely to be shared by his readers.

We are promised a Psychology, but introductory thereto Mr. Lewes has produced two volumes (the second is now under final revision), in which he aspires to lay the Foundation of a Creed. "The great desire of this age is for a doctrine which may serve to condense our knowledge, guide our researches, and shape our lives, so that Conduct may really be the consequence of Belief." Perhaps there is a general, certainly not a universal, longing for something of this kind. The first question is, what is to be the fate of this hunger of the soul? Is this longing doomed to perish for want of an object? or is it destined to be satisfied? If so, how? Religion, thinks Mr. Lewes, is not to die, but to be transformed.

According to Mr. Lewes this new Religion, "Instead of proclaiming the nothingness of this life, the worthlessness of human love, and the imbecility of the human mind, will proclaim the supreme importance of this life, the supreme value of human love, and the grandeur of the human intellect." The first half of this fine sentence is entirely negative; it tells us that the new creed will not seek to suppress or degrade human nature, after the manner imputed to some of the old religions. This is well, and, as it seems to us, sufficient for all that Mr. Lewes, so far as we can make out, has in view.

Before this new doctrine, which is to reconcile the claims of Religion and Science, can be established, it is necessary as a preliminary to transform Metaphysics. Accordingly Mr. Lewes has applied himself to this task. Defining Metaphysics as the "Science of the most general conceptions," to be pursued solely by the method of Science, he discards "all inquiries whatever which transcend the ascertained or ascertainable data of experience." As a name for the province which he thus excludes from metaphysics, he suggests the word *metempirics;* and as *metempirical* has much to recommend it, besides its being the exact correlative of empirical, it will, we hope, establish itself as a useful addition to the language of philosophy. Mr. Lewes anticipates very large results from systematically keeping in view as a principle of research the necessity of clearly and completely eliminating from the statement of each problem all metempirical elements. In the light of this method all mystery, it seems, will vanish from the universe, as the shadows of the morning fly before the rising sun:—"When rationally stated there is no greater mystery in the existence of an external world, or the relations between object and subject, than the relation between activity and waste in the tissues." For, though as Mr. Lewes observes, "it may seem a very bold thing to say," yet he believes and hopes to show that "we not only know that an external Not-self exists,—know it with the same assurance that we know an internal Self to exist, but we also know the manner in which the two are combined in Feeling and Thought." Mr. Lewes will certainly have philosophised to some purpose if he put us in possession of a principle of research that will enable us so completely to transcend what at present appears to be the highest reach of our powers. One condition of understanding the manner of a combination has hitherto been a knowledge of the elements in separation. If we know how oxygen and hydrogen combine to form water, it is because we know these gases otherwise than combined in water. But of the Self and Not-self we know nothing, and can never know anything save as feeling and thought. In the author's own words, "all that we can know of the external is what we have felt or might feel." Nor do we see at this moment that this criticism would lose its point even were we to accept Mr. Lewes's peculiar doctrine of

the subject and object. When explaining how men came to lose faith in the reality of the objective, he points out that by dwelling on the fact that the same subject produces various sensations at different times, they at last "reversed their primary and instinctive judgment, and instead of saying 'qualities belong to objects,' they now said, 'It is we who invest objects with the qualities of our feelings.'" This he seems to regard as giving an undue predominance to the "subjective aspect." We venture to think that it would be more in accordance with the established use of language to describe the error referred to as a failure to observe that the sensations varied, not only with changes in the object, but also with changes in the material organism called our body,—which never was the "*we*" of the philosophers who hold that it is *we* who invest objects with the qualities of our feelings. Looked at from this point of view, the whole truth within our reach is simply this, that with the same external object and the same bodily condition, the same state of consciousness will invariably arise. The peculiarity of Mr. Lewes's position, if we understand it, is that he means by the *Self* the living body, the "sentient organism" *as we know it*, and by the Not-self the external surrounding *as known to us;* for his *reasoned realism* forbids him to seek after any deeper reality of things,—the absolute is what we see and hear. So far are we, as it appears to us, from knowing how the action of external forces on the living organism results in *feeling*, that we cannot make the very least approach to a conception of such a thing. Recognising that each feeling is related to certain vibrations set up in the nervous structure by the action of external agents, which vibrations Mr. Lewes describes as expressed by the feeling, this, as far as we can see, brings us no nearer to a conception of any sense in which "the feeling *is* what it expresses"—is the vibrations. Mr. Lewes will have to say much more than he has yet said, before we shall be able to see with him that stimuli plus mechanism can ever yield an explanation of sensation.

We regret that our space will not permit us to notice any other of the many important topics touched on in this volume. The whole demands, and will fully repay, a careful reading from every student of these matters. Only the first of Mr. Lewes's problems—the Limitations of Knowledge—is worked out at full length, the chapter on Necessary Truths being perhaps the most interesting. In the last chapter Mr. Lewes considers the place of sentiment in philosophy. What he has to show is that Sentiment, or Emotion, is one important source of knowledge. But what he says is more likely to impress his readers with its power of obscuring vision and obstructing research.

DOUGLAS A. SPALDING

OUR BOOK SHELF

Report of the Rugby School Natural History Society for the year 1873. (Rugby: W. Billington, 1874.)

THIS Report is on the whole very satisfactory, and the tone of the preface exceedingly hopeful. At no time in its past history of seven years, the retiring president tells us, does the Society seem to him to have contained more promising workmen. It appears that it has been resolved to construct a geological model of the Rugby district, and for this *magnum opus* many volunteers from the Society have offered their assistance. The appended reports of the various sections are on the whole satisfactory, showing that real work is being done. One of the most valuable features in the Report for 1873 is the number of papers which have been read by the young members themselves, there being seven printed here in greater or less fulness, and a number of others mentioned as having been read at the regular meetings of the Society. One of the most interesting of the published papers is one by Mr. H. N. Hutchinson On Home-made Electrical Apparatus, showing that the author possesses very considerable originality and ingenuity. The apparatus described was made by his brother and himself five years ago, and includes some of the most essential parts of an electrical equipment, the cost of the whole not being more than a few shillings. He thus tells us how the cylinder of an electrical machine may be manufactured. "Choose a tall glass jar, such as you see in confectioners' shop-windows. Next get two wooden caps turned to fit on to the ends of the cylinder, about an inch deep, with projecting pivots. The caps are next to be cemented on to the ends of the cylinder. The cement is composed of resin, beeswax, red ochre, and a little plaster of Paris, and must be heated over a slow fire. The open end of the cylinder must be first covered over with a piece of silk to prevent bits falling in." The conductor was made of deal wood turned to the proper shape and covered very smoothly with tinfoil; the Leyden jars were made from ordinary plum jars. We recommend the paper with its accompanying sketches to those who cannot afford to buy an electrical apparatus. W. B. Lowe describes some carefully made experiments On Cohesion of Water at Various Temperatures; and other papers by pupils, evincing considerable power of observation, are—On an Excursion of Mr. Wilson's Geological Class to Mount Sorrel, by C. M. Kerr; On a Botanical Expedition to Princethorpe, by H. W. Trott; On a Geological Expedition to Atherstone and Nuneaton, by E. Mann; On an Entomological Expedition to Frankton Wood, by H. A. Bull; and On the Chameleon, by J. S. Beuttler, giving an account of the author's own observations on two specimens belonging to himself. Besides these there are several other papers by masters and outsiders; one of the latter is a very instructive paper by Mr. R. H. Scott, F.R.S., On the Weather. The Report also contains four plates by pupil members of the Society.

The Surface Zones of the Globe. A Handbook to accompany a Physical Chart. By Keith Johnston, F.R.G.S. With two Maps and six Illustrations. (W. and A. K. Johnston, 1874.)

THIS little volume will form an interesting and valuable addition to our educational manuals, either as a lesson-book for pupils or as a handbook for teachers. The author divides the surface of the globe into seven great zones, and shows that, without considering the particular species of plants, or the more minute details of the forms of natural life which occur in these belts, and which may differ in one continent from another, there is a resemblance in character throughout the whole extent of each zone, whether of forest, or pasture, or desert, which cannot be mistaken. Mr. Johnston names these zones as follows:—1. The Equatorial Forest Region; 2. The Equatorial Pasture Lands; 3. The Deserts; 4. The Temperate Pasture Lands; 5. The Temperate Forests; 6. The Barren Tundra Regions; 7. The Icy Polar Regions. He describes in detail the characteristic appearance and productions of each region, and in doing so manages to convey a considerable amount of useful information. The manual is intended to accompany a large chart of the world on which these surface zones are distinguished, and a minute copy of which forms one of the diagrams of the work. Another very curious and interesting diagram is intended to show the surface zones on the supposition of a change of 90° in the position of

the earth. The coloured illustrations showing the characteristic appearances of the various zones are as successful as anything of the kind we have seen, although, what perhaps cannot be avoided in coloured illustrations of this kind, there is a little too much of "the light that never was on sea or land" upon them.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Necessary Truths—Physical and other

I AM not about to continue a controversy which I regret having been provoked into by the misrepresentations of one who ignored the contents of works he professed to review. Reply and rejoinder may go on endlessly. I could not, to much purpose, argue with Mr. Hayward, who, instead of taking such unconsciously-formed preconceptions as those resulting from the infinite experiences of muscular tensions and their effects, proposes to exemplify unconsciously-formed preconceptions by a consciously-formed hypothesis concerning the relation between weight and motion. Nor should I care to discuss any question with my new anonymous assailant; who, when certain examples given show the "exact quantitative relations" spoken of to be those of direct proportion, describes me as "intensely unmathematical" because I subsequently use the more general expression as equivalent to the more special—which, in the case in question, it is.

The first of my objects in now writing is to remind "some bystanders, who may from their antecedents be presumed competent to judge," that the essential question is not a mathematical one, but a logical and psychological one, in respect of which I am not aware that senior wranglers, as such, can claim any special competence. Further, even admitting the assumption that the question is mathematical, I have to warn the reader that he will be much misled if he infers that there are not "some bystanders who may from their antecedents be presumed" *more* "competent to judge," who concur in the opinion that the laws of motion cannot be demonstrated experimentally.

My second object is to inclose, for publication in NATURE, a passage now standing in type to be added to future impressions of "First Principles" in further elucidation of necessary truths, and our apprehensions of them.

HERBERT SPENCER

"The consciousness of logical necessity, is the consciousness that a certain conclusion is implicitly contained in certain premisses explicitly stated. If, contrasting a young child and an adult, we see that this consciousness of logical necessity, absent from the one, is present in the other, we are taught that there is a *growing up* to the recognition of necessary truth, merely by the unfolding of the inherited intellectual forms and faculties.

"To state the case more specifically:—Before a neceesary truth can be known as such, two conditions must be fulfilled. There must be a mental structure capable of grasping the terms of the proposition and the relation alleged between them; and there must be such definite and deliberate mental representation of these terms as makes possible a clear consciousness of this relation. Non-fulfilment of either condition may cause non-recognition of the necessity of the truth; and may even lead to acceptance of its contrary as true. Let us take cases.

"The savage who cannot count the fingers on one hand, can frame no definite thought answering to the statement that 7 and 5 make 12; still less can he frame the consciousness that no other total is possible.

"The boy adding up figures inattentively, says to himself that 7 and 5 make 11; and may repeatedly bring out a wrong result by repeatedly making this error.

"Neither the non-recognition of the truth that 7 and 5 make 12, which in the savage results from undeveloped mental structure, nor the assertion, due to the boy's careless mental action, that they make 11, leads us to doubt the necessity of the relation between these two separately-existing numbers, and the sum they make when existing together. Nor does failure from either cause to apprehend the necessity of this relation make us hesitate to say, that when its terms are distinctly represented in thought, its necessity will be seen; and that apart from any multiplied experiences, this necessity becomes cognisable when structures and functions are so far developed that groups of 7 and 5 and 12 can be intellectually grasped.

"Manifestly, then, there is a recognition of necessary truths, as such, which accompanies mental evolution. Along with acquirement of more complex faculty and more vivid imagination, there comes a power of perceiving to be necessary truths what were before not recognised as truths at all. And there are ascending gradations in these recognitions. Thus a boy who has intelligence enough to see that things which are equal to the same thing are equal to one another, may be unable to see that ratios which are severally equal to certain other ratios, that are unequal to each other, are themselves unequal; though to a more developed mind this last axiom is no less obviously necessary than the first.

"All this, which holds of logical and mathematical truths, holds, with change of terms, of physical truths. There are necessary truths in Physics, for the apprehension of which, also, a developed and disciplined intelligence is required; and before such intelligence arises, not only may there be failure to apprehend the necessity of them, but there may be vague beliefs in their contraries. Up to comparatively recent times, all mankind were in this state of incapacity with respect to physical axioms; and the mass of mankind are so still. Various popular notions betray inability to form clear ideas of forces and their relations, or carelessness in thinking, or both. Effects are expected without causes of fit kinds; or effects extremely disproportionate to causes are looked for; or causes are supposed to end without effects. But though many are thus incapable of grasping physical axioms, it no more follows that physical axioms are not knowable *à priori* by a developed intelligence, than it follows that there is no necessity in logical relations because many have intellects not developed enough to perceive the necessity.

"The ultimate physical truth of which clear apprehension is eventually reached, is that force can neither arise without an equivalent antecedent, nor disappear without an equivalent consequent. Along with power of introspection there comes recognition of the fact that existence cannot be conceived as beginning or ending: the Laws of Thought themselves negative any such mental representation. And if it be asked why this intuition, which all physical axioms indirectly imply, and which is postulate in every physical experiment, is to be taken as authoritative because its negation is inconceivable, the answer is that no argument which sets out to discredit it can do this without logical suicide; since there is no other warrant for asserting the dependence of any conclusion on its premisses than the inconceivability of its negation."

This passage forms part of a revised version of the chapters on Matter, Motion, and Force, which I have contemplated making for this year past. When those chapters were written and stereotyped in April 1861 (see Preface), the modern doctrines concerning Force and its transformation were so imperfectly developed, that some of the leading technical words now currently used were not introduced. The reorganisation of "First Principles," which I made in 1867, for the purpose of more truly presenting the general Theory of Evolution, did not implicate these chapters, and I believe I did not even re-read them: the stereotype plates, in common with those of many other chapters, with the numberings of pages and sections altered, were used afresh, and continue still to stand as they originally did. But while now rectifying defects of statement which it was scarcely possible to avoid thirteen years ago, I find no reason for changing the essential conception set forth in those chapters; nor is the need for changing it suggested to me by those on whose judgments I have the best reasons for relying.—H. S.

Royal Society Soirée

WITH reference to your account of the Royal Society's soirée (NATURE, vol. ix. p. 502), will you allow me to explain that all I "promised" concerning the missing pair of Paradise-birds was to deliver them when sent for.

They were not sent for, owing to some mistake, and consequently not exhibited.

May 5 P. L. SCLATER

Father Secchi's Work on the Sun

WITH great surprise I read in NATURE, vol. ix. p. 390, the following note:—

"Father Secchi is preparing at Gauthier Villars a second

edition of his work on the Sun, on an enlarged scale. He has quoted so largely from Mr. Lockyer's 'Solar Physics' that an intended translation of this work is abandoned for the present."

I have the honour to inform you that the complete original of my second edition has been in the hands of M. Gauthier for more than a month, so far as that part which may have something in common with Mr. Lockyer's work is concerned, and that I had not seen Mr. Lockyer's work until a fortnight ago, when I bought it from M. Loescher here in Rome. Mr. Lockyer of course is quoted, but only from his original memoirs, and not from his new publication, nor in such a manner that his publication will render my work useless.

Rome, March 23 P. R. SECCHI

[The following explanation has been sent us by the Paris correspondent who furnished us with the note referred to by Father Secchi:—

"I was told by his (P. Secchi's) editor himself, when I spoke to him about publishing a French edition of Mr. Lockyer's 'Solar Physics,' the substance of what I have written to you. I think that the note I have written is a recommendation of Father Secchi's work; but not so his statement that he did not possess 'Solar Physics' until it was too late to use it. There is nothing whatever dishonourable in quotation."—ED.]

Spontaneous Generation Experiments

SINCE October 1870 I have, as opportunity offered and other work permitted, made a series of experiments bearing on the question of spontaneous generation. They seem to me to tell so plain a story that I am anxious to relate it.

The thoughts which led to the experiments were briefly these:—

The occasional or even frequent presence of living growths in fluids after they have been exposed to a temperature of 212° F. and are contained in closed tubes or flasks is rather an indication of the imperfection of a method than the proof of a theory; for under like circumstances living organisms ought either always or never to develop; the conditions being uniform, the results should be uniform.

When the tubes are closed at a blow-pipe flame after boiling, steam cannot be escaping from the aperture at the time of actual closure, and it is conceivable that in the momentary collapse of the contents which then occurs some atmospheric air containing organic matter may pass into the tube and invalidate the experiment.

The contained air, if any there be after the sealing of the tubes, must be vastly rarefied, and the ordinary atmospheric conditions, other than purity, which are essential, must be absent or greatly modified.

I attempted to devise an experiment which would be free from these possible sources of error; one in which the atmospheric pressure should be normal, in which the physical structure of the air should be unaltered, and in which there should be no chance of organic contamination after heating. Further it seemed a good thing to be able to show at the same time and in the same apparatus two distinct specimens of the boiled fluid, the one exposed only to cleaned air, the other exposed also to common air; and also to use a fluid which would indicate to the naked eye by change of colour, or of clearness, or of consistence, the time at which living growths made their appearance.

The latter condition was secured by using a fluid (for the idea of which I am indebted to Mr. Heisch's experiments on water-impurities) composed of 10 cc. of urine, 1 gramme of white sugar, and 90 cc. of distilled water. This when boiled and filtered is a clear transparent liquid, which becomes milky on the occurrence of organic growth during fermentation in thirty to forty hours, according to the heat to which it is exposed.

The other conditions were effected by using a glass tube of the shape of the capital letter M, with curved bends instead of the angles; a tube which may be described as having four straight legs joined to each other by two loops on the upper side and one on the lower; the first leg closed and the last leg open and short.

This tube, so bent, was made very hot, so as to expel as much air as possible from it; the open end was then plunged into the boiled and filtered urine-sugar fluid, and such a quantity allowed to flow in on the cooling of the tube as left the first, second, and third legs about half full when the tube was held upright. The tube was again heated to the boiling of the contained fluid in order to expel as much air as possible by the generation of steam. It was then allowed slowly to cool, so that the first leg was about one-third filled with fluid; and such an amount was left in the lower loop as would rise in the second and third legs to about the same extent as the tube cooled (and the cooling was designedly prolonged); air passed through the fluid in the lower loop to fill the space in the first upper loop, between the two masses of fluid, left vacant by the condensation of steam.

The tube was then hung up, away from direct sunlight, and exposed to the ordinary changes of temperature of my study.

If I have been able to describe intelligibly this very simple matter, it will be seen that I had here two portions of the same fluid separated from each other; both having been heated to the same temperature and both exposed to atmospheric air.

The conditions were precisely similar with one exception; intentional and crucial. The air in the first upper loop, to which air only the fluid in the first leg was exposed, had passed through and been washed by the fluid in the lower loop; and the fluid of this loop was on one side exposed to the washed air and on the other side to the ordinary atmosphere.

In experiments with this apparatus the phenomena were, in eight cases, as follows:—On the second or third day the fluid in the loop was milky, and the fluid in the first leg was bright. At the end of a week, a month, four months, indeed as long as the tube was kept, the one continued clear, the other was turbid. At the expiration of a time, varying in different experiments from four days to four months, I tilted over the least drop of the turbid fluid in the loop into the clear fluid in the first leg, when at once the milkiness began, and in a day the whole of the leg fluid was turbid also.

In many cases I examined the two fluids, clear and turbid, with a twelfth-inch object-glass, and found Bacteria in the turbid fluid; nothing in the clear fluid.

Twice I left (once unintentionally, once intentionally) so little fluid in the loop that, there being a small aperture, it did not fulfil its purpose as a filter and a valve, and in both cases the two masses of fluid became turbid at the same time.

In six other experiments I used urine; in four instances the loop fluid showed symptoms of putrefaction, and became turbid in four or five days, but the leg fluid remained clear. On the closure of the experiment, at varying periods from a week to four months, the bright urine appeared, on microscopic examination, to contain no organic growth, but underwent putrefaction as ordinary urine when exposed to the air.

In the two other experiments both urines putrefied at the same time. In one case I hastened the cooling by cold; in the other I left very little fluid in the loop.

In four experiments I used Dr. Charlton Bastian's turnip-cheese fluid. In all cases the solution was milky when made; twice it was filtered and twice unfiltered, and in all cases, when examined by the microscope after the lapse of some days or weeks, the fluid in both leg and loop contained organic growth.

The experiments on urine and urine-sugar fluid show, in my view, both positively and negatively, that there is something in the ordinary air which is a necessary condition of the origin of organic growth in these liquids.

Positively this position is demonstrated when, after six months, the fluid in contact with unwashed air is seen to be full of organic growth, and the fluid in contact with washed air is still unchanged.

Negatively it is supported when both fluids are seen to grow turbid at the same time from imperfect washing of the air, by reason of too rapid cooling or too scanty a supply of fluid for the washing.

The experiments with Dr. Bastian's turnip-cheese fluid were for some time a puzzle to me, and made me fear that there was an undetected fallacy in my other experiments. But now it is clear that the contradiction is only apparent. Dr. Burdon Sanderson has shown that this fluid contains within itself the elements of organic growth which are not destroyed at 212° F., the temperature at which my experiments were necessarily conducted.

I am anxious not to press these experiments unduly, but they seem to me to range themselves unequivocally in opposition to the theory of spontaneous generation; although they touch no great extent of the subject.

That the something in the ordinary air necessary for the origin of organic growth in the fluids used is a gaseous impurity of the air is supported by no fact of which I am aware; but whether it be living organised germ or dead unorganised matter, these experiments do not explain or attempt to explain.

LEONARD W. SEDGWICK

The Fertilisation of Fumariaceæ

It was with great pleasure and interest that I read the communications from Mr. Darwin and Dr. Hermann Müller in Nature, vol. ix. p. 460.

It so happens that, since writing the note on the tardy and apparently useless assumption of colour by *Fumaria capreolata* var. *pallidiflora*, I have chanced to see the flowers of this plant visited, on two occasions, by a bee in the daytime.

This insect was, on both occasions, I believe, a mason-bee, and certainly neither a hive nor a humble bee, and, as it confined its attentions to this one variety of fumitory, and was engaged for some time at its work, I had a favourable opportunity of watching the mode of operation.

The bee ranged from plant to plant, but, in every case, would only alight on and suck those flowers which, though still white, had assumed the horizontal position, these flowers alone affording a comfortable landing-stage for the insect.

The bee then clasped the lower part of the tube with its feet, and prized open the flower by thrusting its sheathed proboscis underneath the upper petal, when the tube split lengthwise, and gaped widely open, the style and stamens rising up and emerging from the cap formed by the inner petals, much as they do from the keel in many papilionaceous flowers, and rubbing against the underside of the bee's body.

I may observe that it is precisely in the short period during which the flower maintains itself in the horizontal position that the emission of pollen takes place, and this coincidence of the plant bidding for the visits of insects at that particular moment has much the appearance of special adaptation.

But an examination of the flowers certainly shows that they are capable of self-fertilisation, and Dr. Hermann Müller tells us that Dr. Hildebrand states that this is habitually the case in *F. capreolata*.

I regret that I am only acquainted with Dr. Hildebrand's paper through a review which appeared in the *Bulletin* of the Société Botanique de France, where but few of the details are given.

I have not paid special attention to the structure and habits of the *Fumariaceæ*, and I am therefore unable to say whether the plant to which I have alluded is commonly visited by insects in the daytime, or whether, as Mr. Darwin suggests, its flowers, the nearly white colour of which would render them peculiarly conspicuous in the dusk, may not prove especially attractive to moths and other night-fliers.

While watching the bee whose operations are described above, I noted with interest that it confined its attention exclusively to plants of this single variety of fumitory, winding its way through flowering masses of other fumitories and weeds.

In the same way a honey-bee, at the same spot on a later day, exclusively visited the wild mignonette (*Reseda phyteuma*), passing by the fumitories, marigolds, &c.

J. Traherne Moggridge

Maison Gastaldy, Mentone, April 20

Allow me shortly to resume the different views which have been proposed in your columns, as giving a possible explanation of the fact that the flowers of *F. pallidiflora* attain their brightest colouring when the time for fertilisation has passed, and to point out the observations indispensable to be made, in order to ascertain which of the proposed views is right. 1. It is possible that nocturnal Lepidoptera are the fertilisers of the fumitory; in this case it would be most probable that the pale colour of its flowers has been acquired by natural selection, pale flowers being most conspicuous in the dusk. 2. Diurnal insects may be the fertilisers, and the pale hue may be sufficiently conspicuous or even more attractive for them than the brighter one. In this case, also, the former must be considered as acquired by natural selection; the latter, on the contrary, as in the first case, merely as the result of chemical processes. 3. Under the same supposition of diurnal insects being the fertilisers, it is possible that the older flowers, by their brighter hue, serve to attract insects to the younger and paler ones; in this case the bright hue of the older flowers may be looked upon as acquired under the influence of natural selection, the pale colour of the younger flowers at the same time being useless. 4. It is possible that self-fertilisation is the rule with the flowers of this fumitory, and that cross-fertilisation by insects takes place only very exceptionally; in this case not only, as in No. 3, the paler colour, but also the brighter one would be nearly independent of the influence of natural selection. In order to decide definitely which of these views is right, it is indispensable to watch perseveringly the flower of this plant, and to ascertain what kind of fertilisation naturally takes place. In case diurnal insects should prove by direct observation to be the fertilisers, it would be possible to decide whether supposition 2 or 3 is correct, by removing from many specimens every older flower as soon as its colour begins to grow brighter, and by observing whether these specimens or those with older and brighter flowers are more frequently visited by insects.

It would be a great pleasure to me to make these observations, but I do not know whence seeds of *Fumaria pallidiflora* can be obtained. Perhaps some reader of this letter may be good enough to give me information on this point.

Lippstadt, April 28 Hermann Müller

Mr. Comber's suggestion (vol. ix. p. 484) that the coloured flowers of *Fumaria* attract insects to the uncoloured ones is very ingenious. Supposing that they are cross-fertilised, the case of *Poinsettia* is very pertinent, and is enforced by that of *Dalechampia*, also euphorbiaceous, in which the bracts, a beautiful rose colour before fertilisation, gradually assume afterwards the same green hue as the foliage when the bright colour is no longer needed. The chemical changes that take place in the flower at and after the period of its complete expansion must necessarily be complex, as well as varied in different cases. Rapid oxidation is probably one very effective agent in producing them, but the results will necessarily depend on what is operated upon. *Hibiscus mutabilis* is white in the morning, deep red by night. Species of *Lantana*, like *Myosotis versicolor*, pass through a whole series of colours as they expand. On the other hand all the beautiful species of *Franciscea* rapidly lose the tints with which their flowers open, and become nearly white. The final stages in the life of all the parts of the flower which are not accessory to the formation of the fruit are more or less processes of decay, and there is no absolute law that these should always be accompanied by inconspicuous or displeasing tints. The white flowers of *Calanthe veratrifolia* blacken when they are bruised; on the other hand, according to Kingsley, the crimson flowers of *Couroupita guianensis* turn blue when torn, as the pulp of the fruit is also known to do on exposure to the air. In the same way some fungi exhibit when bruised striking tints which yet can be of no service to them. *Agaricus georginæ* changes from snow-white to blood-red wherever it is touched, and the white flesh of *Boletus cyanescens* when broken changes instantly to the "most beautiful azure blue."

In fact if a chemical change is set up—if it produces a change of tint at all—it must *sometimes* produce a pleasing one; that it should do so is not necessarily advantageous to the plant, though open to be taken advantage of by it.

W. T. Thiselton Dyer

Fertilisation of Corydalis claviculata

With regard to the flowers of *Corydalis claviculata* (of the discovery of which species in this neighbourhood I have sent a note to the *Journal of Botany*), I think Mr. Bennett (vol. ix. p. 484) will find his suspicion that the styles may have been broken off in dissecting to be correct. This may easily be shown by floating off in water the petals, &c., of a withered flower, in which the process of fertilisation has been completed, when the style will be seen adhering to the ovary, though the gentlest touch will be sufficient to separate it. In the bud the anthers cover the stigma, but at the time of maturity the latter projects slightly, so that it would be first touched by the proboscis of an insect. I suspect that it is also slightly protogynous, though self-fertilisation may probably be of frequent occurrence. The manner in which the style is embraced by the stamens and petals protects it from too rough a shock from the struggles of insects in the narrow entrance to the flower. I have not, however, observed them to visit it.

Kilderry, co. Donegal, April 28

Lakes with two Outfalls

Since writing my letter of April 24, with which I forwarded a copy of the new Inch Ordnance map of Arran, I have received other copies from Mr. Stanford, showing, as I presume, that the early copies of General Sir H. James's admirable work have been revised. For, besides the elaborate system of contour lines, which did not appear in the first copies, *two* outlets are given to Loch-na-Davie, instead of one only. So that, as to the "matter

of fact" touching the new Inch Ordnance map, Mr. Christie and I are both right. That is, he has a copy to show for his assertion; I have one to sbow for mine. But the great question is not what is the "matter of fact" as touching maps, but what is the matter of fact in nature; and I assert that Loch-na-Davie has but one outlet, to the south, to Glen Iorsa. My words in the *Athenæum* are—"The water-parting is a few yards to the north of the loch, I should *guess* at the spot where a heap of stones stands, apparently lately thrown up;" and from there there is a slight trickling *inlet* to the loch. I ended my letter thus—"Most gracious reader of the *Athenæum*, go take a tourist ticket to Glasgow from Euston Square. Then a lovely run in a Clyde steamer to Arran, and *judge for yourself*." May I repeat this advice to the "gracious reader" of NATURE, for assuredly there is no *arguing* as to a "matter of fact."

As a matter of opinion, I do not think that any quantity of rain could turn the northern inlet into an outlet. That is, I think that at the southern end there is room to emit any overflow before the northern end could be flooded. Mr. Christie seems to suppose a constant double outlet. Dr. Bryce, more modest, only claims this in "winter and wet summers" (3rd edition, p. 3), or "when it rises about eighteen inches above its level in dry weather" (p. 130).

Alresford, May 1 GEORGE GREENWOOD

I OBSERVE that a correspondence has been going on in the columns of NATURE on the subject of lakes with double outlets. It may interest your readers to learn that some glaciers afford instances of the same phenomenon. One of the most remarkable of these is the Glacier d'Arsine, in the old French province of Dauphiné (now the Département des Hautes Alpes). This glacier is broad and short; its moraines are extraordinarily large. It ends just on the watershed between the Romanche and Guizanne, and consequently streams flow from it in both directions. On one side, the stream forms a branch of the Romanche, which fall into the Drac, the united stream entering the Isère below Grenoble. On the other side, the stream flows down to the Guizanne, which, after receiving the Clairée near Briançon, assumes the name of the Durance, and falls into the Rhone below Avignon. This watershed is a prolongation of that over which the magnificent route impériale (magnificent in point of engineering and of scenery) of the Col du Lautaret has been carried. This glacier is very rarely visited, though the above-mentioned phenomenon has been remarked before. Perhaps some of your readers can supply the names of other glaciers which present a similar phenomenon. I need only add that these observations were made during personal visits to the Glacier d'Arsine on July 15 and 17, 1873.

Exeter College, Oxford W. A. B. COOLIDGE

Trees "Pierced" by other Trees

THE natural phenomenon of one tree within another is very frequently witnessed in India in the case of the "pípal" (vulg. *peepul*) and the palmyra. The first instance which drew my attention to it was one in which a very large specimen of the former with a stem some 4 ft. thick was surmounted by a towering palm which *seemed* to grow out of, and in continuation of, the solid trunk at a height of about 30 ft., and rose to a height of 30 to 40 ft. more. I speak from recollection only. An amicable dispute took place between two natives, of whom I inquired about it—both strangers to the locality—the one declaring that the palm grew up *inside* the tree from the ground, and the other that it grew *upon* it. Subsequently I saw numbers of others in all stages, and recognised the fact that the fig grows up by the side of the palm and gradually *encloses* it, so completely as to defy examination of the resulting trunk. The tree that I speak of was by far the most remarkable specimen of the kind, and therefore I give its locality. It is a little south of the town of Kodangal, in the Hyderabad country, long. 77° 40′ E., lat. 17° 6′ N. J. HERSCHEL

May 5

COLONEL GREENWOOD's solution of the beech-tree pierced by a thorn plant is undoubtedly correct. The New Forest affords many cases of the branches of that tree growing together and forming holes apparently through the trunk. Ivy gives the most striking and familiar examples of its runners crossing and uniting; it is not unusual to find a triangular arrangement of runners which cross each other at intervals of a few inches apart. It may be as well to draw your readers' attention to the spasmo ic way in which the leaves of the beech burst in spring: sometimes an entire branch, at others a single twig with less than twenty leaves, will be in full leaf a week or ten days before the buds have generally burst. G. H. H.

IN reference to this subject I many years ago met with an instance of a birch growing out of the fork of an oak.

The trunk of the oak at perhaps 8 ft. or 9 ft. from the ground divided into two large arms from between which a birch sprung. The oak was of very considerable age but apparently was not hollow (of this, however, I am not positive). The birch was perhaps 12 ft. or 14 ft. high. P. P. C.

The Antipathy of Spiders to the Wood of the Spanish Chestnut

CAN any of your readers establish the truth of the following assertion? Spiders' webs are never found upon beams from the Spanish or sweet chestnut tree, even when the timber is several centuries old. The keeper of the ruins of Beaulieu Abbey, in Hampshire, asserts that this is a fact, and the buildings of the Abbey, where beams of Spanish chestnut are used, are free from the invasion of spiders. His attention was drawn to this four years ago, and since then his observations have not thrown any doubt upon its accuracy.

Birkenhead, April 23 G. H. H.

FLOWERS OF THE PRIMROSE DESTROYED BY BIRDS

WE have received several additional letters on this subject, the important statements in which we have brought together here, in continuation of last week's article (vol. ix. p. 509).

Prof. Newton of Cambridge, in reference to Prof. Thiselton Dyer's letter of last week, writes as follows:—

Allow me to remark that the observation of Gilbert White (quoted by Prof. Dyer in NATURE, vol. ix., p. 509) respecting the bird said to "sip the liquor which stands in the nectarium" of the crown-imperial, has not, so far as I know, been confirmed by anyone else. Yielding to no man in my general trust in White's wonderful accuracy, I think that here we ought to suspend our belief, caution being perhaps the more needed, since, as has been pointed out by several of his editors, it is almost certain that the bird he saw was not the bird he supposed it to be.

Major E. R. Festing writes:—

A month ago I saw a caged hen bullfinch that would treat any quantity of primroses which were given to her in precisely the way described by Mr. Darwin in NATURE, vol. ix. p. 482. She gave one snip only to each flower, not again touching the remains of it, which fell to the floor of the cage.

My experience in trying to keep a small garden in London some years ago was, that the yellow crocus flowers were always destroyed by the sparrows as soon as they come into full bloom, no doubt with the same object as the finches have in destroying primroses. I do not remember that the purple or white flowers suffered in the same way.

A correspondent, dating from Exeter College, Oxford, writes as follows:—

Your article on the destruction of primroses brought to my mind several facts which came under my notice lately in a manse-garden in the south of Scotland. Under a cherry-tree the ground was thickly planted with primroses, all the flowers of which were picked by the sparrows. As not only was this cherry-tree in flower at the time, but there was also a good show of flower on the various other fruit-trees in the garden, in this instance, at least, the flowers of the fruit-trees seem not to have exercised a superior attraction.

Again, I myself saw that the work was done by sparrows.

Another writer in your article asks, if any other birds besides sparrows have been seen to use fresh flowers in nest-building? In this same manse-garden, some weeks ago, I watched some jackdaws busily plucking and carrying to their nests in a neighbouring chimney the leaves, flowers, and stalks of a variegated form of the common *Glechoma hederacea*.

Mr. J. Southwell states that in his garden in the suburbs of Norwich, the yellow crocuses are yearly destroyed by sparrows. He says:—

Formerly I have seen these mischievous birds pulling

the petals in pieces and scattering them on the ground, to enable them to reach the nectary, which is situated about on a level with the soil; but of late they have altered their tactics and simply bruised the perianth tube sufficiently to extract the nectar, leaving the bloom uninjured but fallen over as though killed by severe frost. The primroses have hitherto escaped, but this spring for the first time the sparrows have attacked the blooms of a cherry-tree, bruising the nectary between their mandibles, and generally detaching the blossom from the foot-stalk close to the calyx. That in both cases this is the work of sparrows I have had ample opportunities of observing. Some years ago a border of Virginian stock which was in full bloom appeared mysteriously to be growing thinner every day. I accidentally saw from a window the sparrows vigorously engaged in pulling up the plants, which they could only do by great exertion, and flying off with them to form their nests. This lasted till the whole were carried away. The fact of the sparrows having altered their form of attack on the crocuses, going direct to the nectary instead of pulling the flowers to pieces, would seem to indicate that the habit is acquired, and not inherited; it also appears, so far as I can learn, to be an increasing habit with them.

Mr. A. F. Buxton, of Cambridge, has frequently observed the same fact about primroses in a wood near Ware. He says:—

I could give no satisfactory explanation of the phenomenon, if it were not that I have noticed the propensity of tame bullfinches to act in the same way towards flowers, especially primroses. In the wood I speak of, bullfinches are abundant; but whether or not they are the only birds which act thus I am of course unable to decide.

Mr. W. E. Hart, of Kilderry, co. Donegal, states that the primroses there suffer much every spring in the manner described by Mr. Darwin. The cowslips and oxlips are seldom, if ever, touched. Mr. Hart says:—

The blame is commonly laid upon the chaffinch, though I have only been able to gather circumstantial evidence against it. I have frequently disturbed both chaffinches and greenfinches from primrose-beds, and found the cut-off flowers strewn about. One lady tells me that she once saw a thrush deliberately cut off a number of primrose flowers in her garden, turning each time to stare defiantly at her. Another has frequently seen hedge-sparrows do so. Thus it appears that several different species of birds have acquired the same habit.

J. M. M. has cultivated polyanthuses at Sidmouth, South Devon, for seven or eight years, and each year they have been more or less destroyed by birds, as described by Mr. Darwin. She does not remember to have noticed it till she came to Sidmouth. The wild primroses suffer also, but not, she thinks, to any great extent, though they are abundant in the neighbourhood.

Another correspondent, writing from Poplar, informs us that many years ago he became aware of the fact that flowers containing nectar are attacked by some small animal; having had a bed of crocuses in his garden, the flowers of which were morning after morning destroyed by, he believes, the sharp bills of the sparrows. He, however, suggests that mice frequently might have been the depredators, "as last year," he says, "they destroyed all the grapes in my greenhouse. They are just able to reach such flowers as the crocus and primrose, and they are very hard up at the early season when these delights appear."

M. T. M. mentions, "on the authority of a good observer," that the flowers of the laburnum are sometimes utilised in nest-building by suburban sparrows, "whose destructive habits in the matter of crocuses," he says, "are only too well known to suburban gardeners."

Mr. C. H. Beasley, of Liverpool, writes, that he had a canary some years ago which was particularly fond of primroses, and always bit them in the manner described by Mr. Darwin, usually leaving everything but the part containing the honey untouched. As this peculiarity was exhibited by a domesticated bird, he thinks it highly probable that it was inherited.

THE LECTURES AT THE ZOOLOGICAL SOCIETY'S GARDENS

III.

MR. SCLATER commenced his fifth and concluding lecture on the geographical distribution of the mammalia, by impressing the importance of precise definition of the exact localities from which zoological specimens are obtained. He showed that by further careful collecting, new animals, even of considerable size, most probably remain to be discovered, considering that a previously unknown rhinoceros and a fresh genus of deer had been made known within the last three years.

The importance of the geographical distribution of the larger divisions of the mammalia is well illustrated in the case of the *Bassaris* of Mexico, an animal supposed for a long time to belong to the civet cats, which are peculiar to the Ethiopian and Indian regions, but now known in its internal structure to agree with the racoons, which are typically American forms. So also the so-called musk deer are often said to inhabit northern Asia, India, and Africa, but there is only a single species of the true musk deer, which is from northern Asia, whilst the Tragulidæ (with which it has been erroneously united) form quite an independent group, found in India and Africa.

The facts given in the preceding lectures suggest the question as to how the world may be most naturally divided according to the distribution of the animal life upon it, which is part of the great problem of the distribution of organic life generally; and it is evident that all great deductions made from any one group must in the long run correspond with those from other groups.

At the outset it is evident that the ordinary geographical divisions of the world do not hold. Europe must be combined with the northern part of Asia, and also with Africa north of the Atlas Mountains. In the same way central America and part of Mexico have to be included with South America. Taking the division of the mammalia into Monodelphs, Didelphs, and Ornithodelphs, the peculiarities of their distribution are very instructive: dividing the surface of the earth into four major divisions —1. *Arctogæa*, or North Land; 2. *Dendrogæa*, or Tree Land; 3. *Antarctogæa*, or South Land; and *Ornithogæa*, or Bird Land.

Arctogæa is divisible into four minor regions—(α) the Palæarctic, (β) the Ethiopian, with the Lemurian subregion of Madagascar, (γ) the Indian, and (δ) the Nearctic. The Palæarctic region possesses few characteristic families and genera. Its boundaries, as are those of all regions except when sea-bound, are ill-defined; Palestine, for example, is doubtful. Quadrumana are almost entirely absent; *Rhinopithecus*, a Thibetan form, belonging, apparently, to the region. The genera *Ælurus* and *Capra* are characteristic forms. Bears are mostly confined to it, some being, however, found in North America and one in South America. Among the Ungulata, the genus *Equus* is more truly Palæarctic than otherwise, and *Cervi* are abundant.

The Ethiopian region embraces Africa south of the Sahara. The genera Troglodytes, Colobus, Cercopithecus, and Cynocephalus are characteristic, as are Hyæna, Proteles, Lycaon, Hippopotamus, Camelopardus, and others. Madagascar forms a well-marked sub-region, containing no antelopes nor cats, but Lemur, Chiromys, and Cryptoprocta. It is the true home of the lion.

The Indian region extends along Southern Asia to Wallace's line in the Malay Archipelago. The only ruminant animal in the Indian Archipelago is the peculiar *Anoa depressicornis*.

The Nearctic region is very much like the Palæarctic. Castor, Gulo, and Lynx are common to the two. Taxidea, Procyon, and Antilocapra are characteristic, whilst Didelphys has entered from the south.

The Neotropical region (*Dendrogæa*) possesses great individuality, Cebus, Hepale, Icticyon, Nasua, and

Cercoleptes being characteristic. Hystricidæ abound, and Ruminants are very badly represented, only lamas, peccaries, and tapirs being found. Sloths, armadillos, and opossums are not found elsewhere, and there are no frugivorous bats, Insectivores, Viverridæ, nor elephants. The West India Islands form a well-marked (Antillean) sub-region, possessing Solenodon, and peculiar Rodents.

The Australian region, including Australia and the Malay Archipelago up to Wallace's line (or *Antarctogœa*), is characterised by the presence of the Monotremes and Marsupials. Lastly New Zealand (*Ornithogœa*) has no Mammals at all except two Bats.

Mr. Sclater, in conclusion, explained the different answers which had been given to the question: Why are animals thus distributed? showing that the Darwinian hypothesis is a key to the whole subject, rendering quite simple most of those difficulties which were previously insurmountable.

CAMPHOR

THE camphor of commerce, it is well known, is the produce of *Camphora officinarum* Nees., a tree of China and Japan. To obtain it the wood is cut up into pieces and boiled in water, when the camphor is deposited. It is afterwards purified by sublimation, and further refined after its arrival in this country. Immense quantities of this article are imported from Singapore, and though so valuable in European commerce, in Sumatra and Borneo a much higher value is put upon that known as Sumatra camphor, which is obtained from *Dryobalanops aromatica* Gaert. (*D. camphora* Coll.), which does not come to this country as an article of trade. Besides these there is a third kind of camphor, known in China as Ngai camphor; this, in point of value, stands between the ordinary commercial article and the Malayan or Sumatra camphor. Its botanical source has for a long time been doubtful, but it has generally been attributed to an unknown species of *Artemisia*. Mr. D. Hanbury, however, who has done so much in clearing up doubts on the botany of many of our important articles of trade, more especially in relation to drugs, has recently, in a paper read before the Pharmaceutical Society, identified the plant with *Blumea balsamifera* D.C. It is a tall, herbaceous plant, and has long been known for the powerful smell of camphor emitted from the leaves when bruised. It is common in Assam and Burma, and indeed throughout the Indian islands.

The materials from which Mr. Hanbury has been enabled to solve the problem of the origin of this peculiar camphor were sent him from Canton, and consisted of a small branch of the plant, and specimens of the camphor itself. These specimens, he says, "represented two forms of the camphor—the one a perfectly colourless crystalline substance, in flattish pieces as much as an inch in length;" the other, which was sent as crude camphor, was a crystalline powder of a dirty white colour, mixed with some fragments of vegetable tissue. "The purer sample has an odour scarcely distinguishable from that of ordinary camphor; but the odour of the other is perceptibly contaminated with a smell like that of wormwood." This camphor, though seldom seen in this country, was at one time attempted to be brought into commerce, one hundred pounds of it having been made in Calcutta. It is used in the East, both in medicine and in the manufacture of the scented Chinese inks. It is stated that "about 15,000 dols.' (3,000*l*.) worth is annually exported from Canton to Shanghai and Ningpo, whence it finds its way to the ink-factories of Wei-chau and other places."

Though it is now proved that *B. balsamifera* is the plant yielding the bulk of Ngai camphor, it is not improbable that some other plants lend their aid, for the term "Ngai" is, it appears, applied to several belonging to the Labiatæ and Compositæ. JOHN R. JACKSON

THE "SPAR CAVES" OF THE NORTH BRIDGE, EDINBURGH

THE North Bridge, which spans the deep valley lying between the Old and New Towns of Edinburgh, was built upwards of a hundred years ago, and its huge arches must be familiar to all who have entered Edinburgh from the south by railway, the terminus for the main southern lines being situated just below. Between the arches of the bridge and the roadway above are a number of chambers or vaults which have not been opened, till recently, since the bridge was built. In carrying out the operations necessary for the widening of the now too narrow bridge, these vaulted chambers have been opened up, and one of them has been visited by Prof. Geikie, who, in a communication to the *Scotsman*, describes the wonderful sights he saw.

"The chamber we examined," he says, "was about eight or ten feet broad, and varied in height according to the rise and fall of the floor over the arch underneath, the floor coming sometimes so near the roof that we needed to stoop low to get through. From the vaulted ceiling, and especially from the joints of the masonry, hung hundreds of 'stalactites'—delicate spar icicles of snowy whiteness. In many cases they reached to the floor, forming slender thread-like pillars. In making our way we were under the necessity of brushing down many of these pendant masses. Now and then we seemed to be marching through a grove of white and brittle canes. The longest entire one we could see measured rather more than six feet in length. Usually they were slim stalks somewhat like thick and not very well-made tobacco-pipes, but towards the sides of the vaults they became thicker and stronger, one which we carried off measuring about four feet in length, and as stout as an ordinary walking-stick. The same material as that forming the stalactites spread in ribbed sheets down the sides of the vault. The floor, too, was dotted all over with little monticules of the same snow-white crystalline spar.

"A more illustrative example of a stalactitic cavern could not be found. The whole process was laid open before us in all its stages. Along the joints of the masonry overhead could be seen here and there a drop of clear water ready to fall. At other places the drop hung by the end of a tiny white stone icicle, to which it was adding its own minute contribution as it evaporated. From the mere rudimentary stumps the stalactites could be traced of all lengths until they were found firmly united to the spar hillocks on the floor. Every one of these hillocks, too, lay directly beneath the drip, catching the remainder of the stone dissolved in the dropping and evaporating water. In every case the stalactites were tubes; even the thickest of them, though it had undergone great changes from deposit on its outer surface, retained, nevertheless, its bore. Usually there hung a clear water-drop from the end of the stalk, ready to descend upon its white stony mound beneath.

"So far, except for the undisturbed perfection of the whole, there was nothing which may not be seen under many an old vault. But what astonished me most was the evidence of a continuous growth and destruction of these slim stalks of stone during an actually known period. In a great many cases the little 'stalagmite' mounds were each surmounted by a short slender stalk, as the Calton Hill is by Nelson's monument. There could be no doubt that these monumental-looking objects were merely the lower ends of once-continuous stalactite pillars. And indeed, searching round the mound I could usually find fragments of the broken column imbedded in the growing stalagmite. What had broken them? Perhaps a heavy omnibus thundering overhead, or a laden lorry or a deftly-fired royal salute. Anyhow, for a hundred years

this delicate tapestry has been hanging and growing, and breaking and growing again, quietly in darkness, beneath the grind of our carriage wheels, and yet high in air, with the stream of human life flowing underneath it too. Alike in the pendant stalks, on the walls, and in the mounds on the floor, the prevailing colour of the crystalline incrustation is pure white. These caves in middle air have been shut up from the contamination from town smoke. Now and then, however, the dripping water has come upon soluble iron as well as lime. Hence the mounds on the floor are sometimes curiously coloured yellow, brown, and red.

"As the bridge is built of sandstone, wholly or almost wholly free from lime, it is evident that the material which has converted these vaults into such picturesque caverns has been derived from the mortar. All rainwater, as is well known, takes up a little carbonic acid from the air, and of that acid there is in the air of a town usually more than the normal proportion. Filtering through the masonry, it dissolves the lime, carrying it downward in solution, and, if made to halt and evaporate, depositing it again in the form of the white crystalline substance which we call spar. It would be a curious question for the architect how long his masonry could resist this action. Certainly, in spite of what these vaults in the North Bridge reveal, the masonry of that structure is to all appearance as solid and firm as ever. It is evidently impossible, however, that the mortar, if necessary at all, can be piecemeal removed without in the end causing the destruction of a building."

REPORT OF PROF. PARKER'S HUNTERIAN LECTURES "ON THE STRUCTURE AND DEVELOPMENT OF THE VERTEBRATE SKULL" *

III.

IN the types already considered, the exo-skeleton consists of small placoid scales having the structure of teeth, and imbedded in the skin, but being altogether irrelative to the true cartilaginous endo-skeleton. In the group of fishes which form so perfect a mean between these Elamobranchs and the osseous fish—the Ganoids—the body is covered with close-set "ganoid" scales, which consist of two layers, a deeper one of bone (dermostosis), and a superficial one of enamel, covered only by a thin layer of epidermis. In the head these scales pass insensibly into a set of bones in close relation with the chondro-cranium, and having the connections, positions, &c. which characterise the roofing-bones of one of the higher skulls (parietals, frontals, nasals, &c.). In many cases these bones are so deeply imbedded in the subcutaneous tissue as to deserve the name rather of parostoses than of dermostoses, but are always easily removed by maceration or boiling. They are evidently of an entirely different nature to another series found in the same skulls, but in intimate connection with the cartilage, and only separable by its entire destruction. These last are ossifications of the chondro-cranium, and are often spoken of as "cartilage-bones;" the former kind have only a secondary relation to the primordial skull, and are known as "membrane-bones."

In the osseous fish both these varieties of bone appear, but the investing or membrane-bones are all true parostoses developed in the deeper subcutaneous tissue, and the place of the ganoid dermostoses is taken by cycloid or ctenoid scales. Still the insensible gradation between scales and skull-bones is very apparent: along the side of the trunk passes a series of curious tubular or grooved bones containing mucous glands and known as the "lateral line series;" these, on reaching the head, branch out so as to produce a tree-like arrangement instead of a single row, and the burrowing is now, not in a set of modified scales, but in true cranial bones, some belonging to the opercular apparatus, some to the series above and below the eye.

IV.—*Skull of the Salmon* (Salmo salar).—In the Teleostean the investing bones attain a greater development than in any other group, and, in the description of the salmon's skull, will be considered before the cartilage-bones which they overlie, and from which they come away with great ease by maceration.

There are, in the first place, on the upper surface of the skull, three pairs of bones and a single median ossification. Of these, a pair of small bones, separated from one another by a considerable interval, and lying over the auditory region, answer to the parietals (Fig. 7, Pa); a much larger pair roofing over all the central portion of the brain case, from the parietals behind to the nasal region in front, are the frontals (Fr); and a very small and insignificant pair situated just above the nasal sacs the nasals (Na). All these are well known from their occurrence in the higher animals; but the bone marked S.Eth (super-ethmoid), which lies between the nasals and over the cartilage separating the olfactory organs, is peculiar to certain osseous fishes.

Above the eye is a small bone, known as the supra-orbital (S.Or), and below and at its sides a chain of bones, deeply excavated by slime-glands, the sub-orbitals (Sb.Or); the most anterior of these (Lch) seems to answer to the lachrymal bone of the higher animals. The gape of the mouth, instead of being formed, as in the shark and ray, by the naked pterygo-palatine and Meckelian cartilages, is bounded entirely by membrane-bones, three in the upper jaw, the pre-maxilla (Pmx), maxilla (Mx), and malar or jugal (Ju), and one in the lower, ensheathing Meckel's cartilage, the dentary (D). The maxilla, unlike that of most typical Teleosteans is dentigerous, and takes a large share in the formation of the gape. Immediately below the angle of the lower jaw is situated a small bone, the angular (Ang).

Two very important parostoses occur on the under surface of the skull, where they clamp and strengthen the cartilage; these are the vomer (Fig. 8, Vo), which bears a few teeth, and the para-sphenoid (Pa.S), the enormous development of which is so characteristic of the bony Ichthyspsida.

Lastly there are the bones supporting the gill-cover, or operculum proper, and branchiostegal membrane, each of which has its own set of osseous strengthenings. In the first set are included the opercular (Op), sub-opercular (S.Op), pre-opercular (P.Op), and inter-opercular (I.Op); in the second, the branchiostegal rays (Brs.R). The operculars are also divisible into two categories; two of them—the pre- and inter-opercular—are developed in the fold of skin growing from the mandibular arch, which covers the cleft (existing only in the embryo) between it and the hyoid (Fig. 1, p. 425, Ty.Eu), while the remaining two belong in like manner to the operculum of the hyoid arch covering the branchial slits (Fig. 1, Cl^1). The pre-opercular is interesting as being the homologue of the lower part of the mammalian squamosal, and the inter-opercular as representing the tympanic, the two membrane-developed ossifications of the complex temporal bone of human anatomy. The branchiostegal rays are flat sabre-like bones, twelve in number, attached to the hinder edge of the hyoid apparatus. In most Teleostei these bones are seven slender terete rays, the four upper of which are attached to the outer and the three lower to the inner side of the hyoid. At the point where the branchiostegal membranes of opposite sides meet below the throat a median ossification is developed in the subcutaneous tissue; this is the so-called uro-hyal, or basi-branchiostegal (B.Brs).

* Continued from vol. ix. p. 468.

When all the foregoing bones are stripped off, the salmon's skull is far more comparable than in its perfect state with that of an Elamobranch, being reduced to the chondro-cranium, a cartilaginous structure, with certain endogenous ossifications, but retaining to a remarkable extent the characters of a "primordial skull." A side view of the chondro-cranium is shown in Fig. 9 : viewed from above it presents, like that of the ray, expanded sense capsules, and a narrowed inter-orbital region ; the walls of the brain-case are, however, much thicker, and its cavity relatively smaller than in the preceding type (see Fig. 8) ; the rostrum also is short, and the roof of the skull or tegmen cranii produced into a strong ridge (culmen cranii). The end of the snout divides into two short processes (hypo-trabeculars, H.Tr), on each of which two labial cartilages are borne (l^1, l^2).

The bones developed in the chondro-cranium of the salmon very rarely come together so as to form sutures, but are usually separated by considerable tracts of cartilage or synchondroses. Ankylosis only takes place in the case of a single pair of bones—the orbito-sphenoids—which are fused together in the mid-line, so as to form a structure not unlike the "girdle-bone" of the frog.

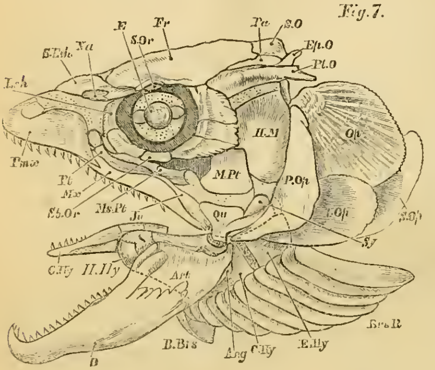

FIG. 7.—Skull of Salmon. Pa, parietal ; Fr, frontal ; Na, nasal ; S.Eth, supra-ethmoidal ; S.Or, supra-orbital ; Sb Or, sub-orbitals ; Lch, lachrymal ; Pmx, pre-maxilla ; Mx, maxilla ; Ju, jugal ; D, dentary ; Ang, angular ; Op, opercular ; S Op, sub-opercular ; I.Op, inter-opercular ; P.Op, pre-opercular ; Brs.R, branchiostegal rays ; B.Brs, basi-branchiostegal ; S.O, supra-occipital ; Ep O, epiotic ; Pt.O, pterotic ; Pl, palatine ; Ms Pt, meso-pterygoid ; Art, articular ; Sy, symplectic ; G Hy, glosso-hyal. The cartilaginous parts are dotted.

The hinder or occipital region of the skull is ossified by four bones, which surround the foramen magnum, and together form the "occipital segment ;" these are the basi-occipital (Figs. 8 and 9, B.O) below, the exoccipitals (E.O) at the sides, and the supra-occipitals (S.O) above. The first of these bears a concave surface or condyle (O.C) for articulation with the first vertebra, the space between the two being filled up with the remains of the notochord. The auditory capsules are strengthened by no less than five bones : the prootic (Pr.O) formed in the anterior part of the capsule ; the opisthotic (Op.O) over the ampulla, and the epiotic (Ep.O) over the arch of the posterior semicircular canal ; the pterotic (Pt.O) over the arch and ampulla of the horizontal, and the sphenotic (Sp.O) over the ampulla of the anterior canal. The prootics of opposite sides meet in the mid-line (Fig. 8), and form a bridge of bone on the base of the skull, in front of the basi-occipital. Anterior to this "prootic bridge," and completing the basis cranii, is a small bone, Y shaped in section, the basi-sphenoid (B.S), which, curiously enough, has no cartilaginous predecessor, but is ossified directly from membrane. Above this bone, and in front of the sphenotic, the ali-sphenoids (As) are found in the side-walls of the brain-case, and, together with the basi-sphenoid below and the parietals above, form the "parietal segment" of the skull. The "frontal segment" has no basal element, the pre-sphenoid being absent, but its side-pieces are represented by the coalesced orbito-sphenoids (O.S) The only remaining bone in the skull proper is the large lateral ethmoid (L.Eth), which occurs immediately behind the depression for the nasal sac (Na).

Certain very constant relations exist between these bones and the cranial nerves. The trigeminal (V.), for instance, always determines the prootic, as its third division makes its exit just in front of that bone, or, in other

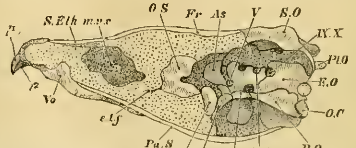

FIG. 8.—Longitudinal section of Salmon's Skull. Pa.S, para-sphenoid ; Vo. vomer ; B.O, basi-occipital ; E.O, exoccipital ; Pr.O, prootic ; B.S, basi-sphenoid ; As, ali-sphenoid ; O.S, orbito-sphenoid ; O.C, occipital condyle ; l^1, l^2, labial cartilages ; m.n.c, middle nasal cavity ; e.t.f, ethmo-trabecular fissure.

words, between the anterior boundary of the auditory capsule and the parietal segment. The glosso-pharyngeal and vagus (IX. and X.) in like manner limit the posterior boundary of the ear capsule, passing out either between it and the exoccipital, or through the front part of the latter. The optic nerve (II.) passes between the parietal and frontal segments, usually being bounded in front by the orbito-sphenoid, and behind by the orbito-sphenoid. In the salmon a bar of bone grows across the trigeminal notch of the prootic, so that part of the nerve passes through a complete foramen.

An interesting instance of the retention of embryonic characters is seen in the slit marked e.t.f in the sectional view, Fig. 8. This is a fissure in the otherwise solid cartilage running forwards for a short distance from the lower anterior angle of the orbito-sphenoid, and indicating

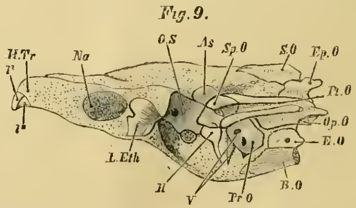

FIG. 9 —Skull of Salmon, with investing bones and facial arches removed. Op.O, opisthotic ; Sp.O, sphenotic ; L.Eth, lateral ethmoid ; H Tr, hypo-trabecular.

the line of separation between the trabecular portion of the skull and the part produced by the chondrification of its originally membranous walls ; this structure is called the ethmo-trabecular fissure. In front of and above this fissure is a large cavity (m.n.c) filled with fat, and opening on the surface of the chondro-cranium beneath the supra-ethmoidal bone ; there is no doubt that this seemingly useless space represents the single nasal chamber of the lamprey or hag.

The structure of the facial arches, and the chief points in the development of the salmon's skull, will be considered in the next paper.

(*To be continued.*)

THE COMING TRANSIT OF VENUS*

III.

IN the previous articles various methods have been indicated by means of which we may discover the scale upon which the plan of the solar system is drawn. The last article concluded by illustrating the nature of the methods of employing a transit of Venus, as proposed by Halley. It will be noticed that this method can be utilised in the way there indicated only when Venus passes nearly across the diameter of the sun. Halley, in fact, founding his calculations upon erroneous data, was led to conclude that this would be the case in 1761. In this he erred, and another slight but important mistake having been made in his calculations, it followed that at Hudson's Bay, his northern station, the transit was invisible.

The present article will be devoted to a description of the methods to be employed in the coming transit for determining the solar parallax. In subsequent articles the

FIG. 11.

preparations which have actually been made for observing the transit of 1874 will be described; and the difficulties encountered in this kind of observation enumerated.

Let the reader now examine Fig. 11 and pay particular attention to the description of it, and he will thus be enabled better to understand what follows. The earth, Venus, and the sun are here represented in their relative positions; and lines are drawn to show the directions in which two observers at opposite sides of the earth will see Venus upon the solar disc. It follows from this that an observer on the southern portion of the earth will see Venus trace a path D E F upon the sun's disc farther north than the path A B C which a northern observer on the earth sees it trace. Now Venus will be three times as far from the sun as from the earth on that date. From this it follows that the distance between the two lines A B C and D E F will be three times as great as the distance N S. But the distance N S upon the earth can be

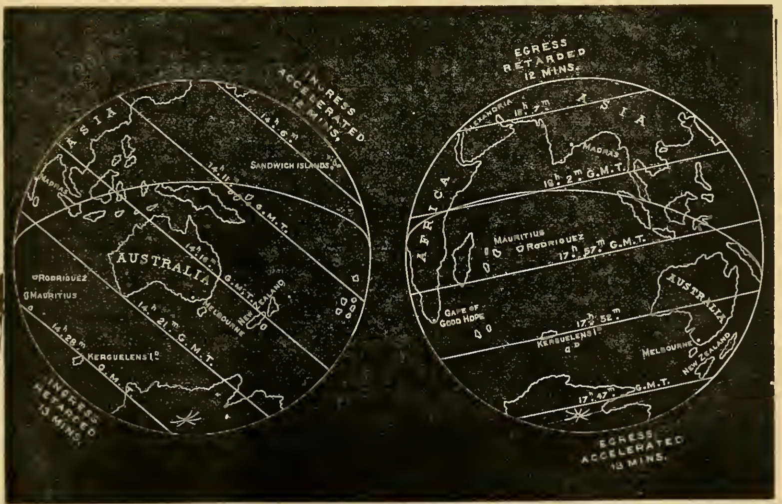

FIG. 12.

easily found out. Suppose it to be 6,000 miles. In that case the distance between A B C and D E F is known to be 18,000 miles. But it needs no demonstration to convince us that if we have a distance of 18,000 miles measured out for us upon the sun's surface we can determine the distance of the sun from the earth.

Now the apparent distance between the two lines A B C and D E F is the least observed distances between Venus' centre and the sun's during the transit. *If then, we can measure accurately the least distance between the centres of Venus and the sun, at two stations suitably chosen, we can determine the sun's distance.*

There are three methods by means of which this may

* Continued from vol. ix. p. 489

be effected; the photographic method, the heliometric method, and the method of durations. We shall consider these in order.

I. *The Photographic Method.*—It is easy to see that by continuing during the transit to take photographs of the sun, in which Venus will be represented as a black spot, these photographs may be so combined as to indicate definitely the apparent path of Venus as seen at these two stations. This method is looked forward to with much interest, because it is the first time that photography has been extensively employed in delicate astronomical measurements. It is not generally known how extremely accurate a means of observation photography is. We owe much to Mr. De la Rue, whose success in the application of photography to astronomy has been unequalled, for having given us a most clear account of what has been done in this way.* The method has been employed in America to measure the distances between double stars. The double star is photographed and the distance is afterwards measured as accurately as possible. Prof. Bond finds that the probable error of such a measurement is 0″·072 or $\frac{1}{3}$ of the probable error of a similar measure made with a filar micrometer as estimated by Struve. Photographic pictures of the sun were for many years daily taken at Kew, and it was found that an extremely accurate measure of the sun's diameter could thus be made. If the lens of a common telescope were used to produce an image of the sun upon the sensitive plate the picture would be too small for accurate measurement. Hence a special instrument called a photoheliograph must be devised to give an enlarged picture upon the sensitive plate. Two perfectly distinct kinds of instruments are to be used for this purpose, the one English, the other American. Mr. Dallmeyer has, under the superintendence of Mr. De la Rue, constructed photoheliographs for the English and Russian expeditions. In these instruments the image of the sun produced in the focus of an ordinary telescope is enlarged by a special arrangement so as to give a picture of the sun about four inches in diameter. This instrument, based upon the principle of the Kew photoheliograph, is very perfect in its results and convenient in actual practice. It is mounted equatorially so as to follow the motion of the sun. The sensitive plate, which is prepared in an adjoining room, can be readily inserted and exposed. The intensity of direct solar light is so great that special means are necessary to give a short enough exposure. Before a photograph is taken a sliding shutter in the interior of the instrument cuts off all light from the sensitive plate. This shutter is held in its place by a cotton thread. So soon as this thread is cut, a strong spring draws down the shutter, in which is a slit about $\frac{1}{40}$th of an inch wide. The time taken by this slit to pass over any part of the sun's image is the whole interval required for an exposure.

The other method of obtaining a large picture of the sun is by employing a lens of great focal length. This method was originally proposed by Mr. Rutherford, of New York, and will be employed by the Americans, and also by Lord Lindsay in his observations at the Mauritius. The focal length of the lens is forty feet. But a telescope of such dimensions could not be conveniently mounted in the ordinary way. To overcome this, a siderostat similar to the one originally constructed by M. Foucault for the Observatory of Paris is employed. This instrument consists of a plane mirror so mounted as to send the sun's rays always in the same horizontal direction. In the path of these rays, and close to the siderostat the lens is placed, and at a distance of forty feet an image of the sun about four inches in diameter is produced. At this place a window is arranged in the photographer's hut, and by means of this arrangement the photographer need never leave his dark room. After preparing a plate he places it in position at the window; when exposure has been made he may remove the plate and develop it.

* Address to the Mathematical and Physical Section of the British Association, Brighton, 1872.

Considerable advantage is likely to accrue to the employment of dry plates, which will diminish the labour of the photographer. Researches upon this matter have been undertaken by Prof. Vögel, in Holstein, Col. Smysloff, at Wilna, and by Capt. Abney, at Chatham. The employment of a dry process prevents all danger from the shrinking of the collodion-film. Herr Paschen * and Mr. De la Rue have made experiments upon this point. The latter gentleman finds that all shrinkages take place in the thickness of the film, so that the measurements would not be affected by it But the more convenient dry plate process is undoubtedly safer. Judging from the data furnished by Mr. De la Rue, this photographic method will give results of the utmost value.

II. *The Heliometric Method.*—The exact measurement of the distances of the edges of Venus from opposite edges of the sun would enable us easily to determine what is required, viz., the least distance between the centres of the sun and planet. But the ordinary astronomical means are useless in measurements of this magnitude. To obviate this, a special instrument, called a heliometer, will be employed by the Germans and Russians, and by Lord Lindsay. This instrument was originally invented for measuring the diameter of the sun. The object-glass of a common telescope is divided so as to form two semicircles. A screw adjustment allows us to slip one-half of the lens past the other one along their line of junction; a fine scale measures this displacement. When the two halves of this object glass are relatively displaced, two images of the sun are seen overlapping. The distance between the two images is proportional to the relative displ cement of the two halves of the object-glass. This instrument has been brought to a state of great perfection by Mr. Repshold, of Hamburg. It is a very troublesome instrument to manipulate, and the corrections due to the influence of temperature are extremely difficult to apply. Yet with great care there is little doubt that very accurate measurements can be made. The nature of the measurements required to obtain the distance between the centres of Venus and the sun will readily be understood. The method has been most ably discussed by Lord Lindsay and Mr. Gill in the Monthly Notices of the R.A.S., November 1872. At the same time it is difficult to conceive that this direct method will give results of equal value with the methods hereafter described. In fact, an opposition of Mars would be expected to give equally good results; for the distance of Mars from a fixed star can be more accurately observed with a micrometer than the distance between the centres of Venus and the sun; and a larger number of observations could be made.

III. *The Method of Duration.*—The third method of determining the least distance between the centres of the sun and Venus is less direct than either of the preceding methods; but it has stood the test of a previous trial, and we cannot say but that it will be more satisfactory than the other methods in the coming transit. The method of duration closely resembles the method originally proposed by Halley. The duration of the transit, as viewed from two distinct stations, is accurately determined. But the difference in this duration is affected by choosing stations upon a different system. Nevertheless this method is frequently called Halley's method. His method consisted in choosing two stations, so that during the transit the one should be moving eastward and the other westward. It is further essential for success that Venus should pass nearly along the diameter of the sun. In the method employed last century, the two stations were chosen—the one far north, and the other far south. On referring to Fig. 11 it will be seen that in each case Venus appears to pass along a chord of the sun. But in

* *Astronomische Nachrichten*, 1872, lxxix. 161.

the one case this chord is farther from the sun's centre, and consequently shorter than the other. The duration of the transit, so far as this effect is concerned, is directly proportional to the length of the chord traced out by Venus. Thus from observation we obtain the lengths of these chords; and by geometry we can deduce the least distance between the centres of the sun and Venus at each of the two stations, and hence we can determine the sun's parallax. Fig. 12 illustrates this point very clearly. The duration is determined by two distinct observations made at each station, the internal contact at ingress and the internal contact at egress. The time of an internal contact is the time at which Venus appears to be just wholly within the sun's disc. These two times must be accurately determined; they will be separated by an interval of nearly four hours. Fig. 12 represents the illuminated hemispheres of the globe at the time of ingress and at the time of egress respectively in 1874. At either of these epochs the sun will be visible from every place marked on the corresponding map. The sun will be vertical at the place occupying the centre of the map; at all stations near the edges of the map the sun will at that time be near the horizon. The point from which the phenomenon will be first observed is there indicated, and likewise the point at which it is last seen. Straight lines are drawn across each map, and the hours marked upon them indicate the time at which the phenomenon will be seen.

Fig. 13, taken from Lockyer's "Popular Astronomy," shows the same facts for the transit of 1882.

Take now the case of two particular stations. At some point on the east coast of China the ingress is accelerated by 6 minutes, but at the same point the egress is retarded 7 minutes; consequently the duration of the transit is lengthened 13 minutes. Again, at Kerguelen's Island the ingress is retarded 10 minutes, while the egress is accelerated 5 minutes. Here then the duration of the transit is shortened 15 minutes. The difference in duration as observed from these two stations will therefore be about 28 minutes. These maps have no pretension to great accuracy. They are calculated upon a certain assumption as to the value of the solar parallax which is probably not far from the truth.

In 1761 considerable preparations were made for observing the transit of Venus in this manner. The English were represented by Messrs. Mason and Dixon at the

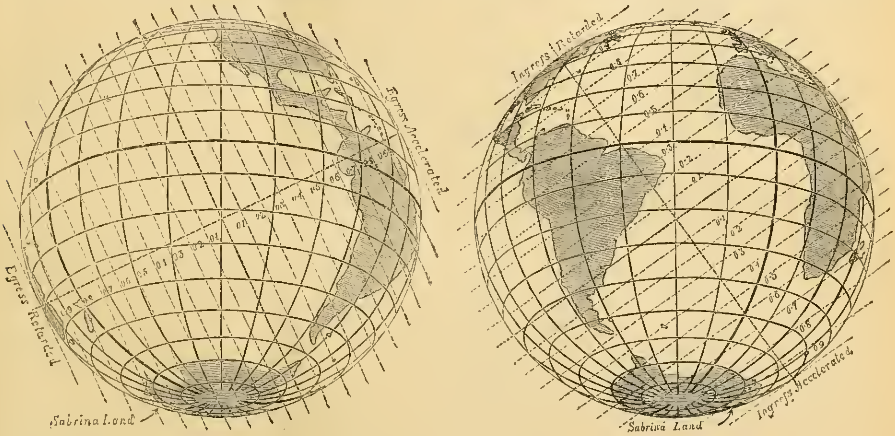

FIG. 13.

Cape of Good Hope, and the French by the celebrated Pingré at the island of Rodriguez. A host of observers watched the phenomenon from northern regions. Unfortunately at scarcely a single station was the transit seen completely. Hence the method of durations was inapplicable, and another, originally proposed by De l'Isle,* came into use. This takes advantage of the fact that the ingress will take place later when seen from some parts of the earth than from other parts, as explained above; so with the egress of the planet from the sun's disc. Hence, if the absolute time of contact of Venus with the sun's edge at ingress or at egress be observed at two places suitably chosen, the difference in time will be a measure of Venus's parallax.

The method of De l'Isle will perhaps be better understood by looking upon the orbit of Venus as a vast protractor for measuring small angles. Venus passes relatively to the earth round the sun, that is through 360° in 584 days. From this it follows that she passes over $1''\cdot 5$ in one minute of time. Now conceive two straight lines to be drawn from the sun's edge, the one to the Sandwich Islands, where the ingress is most accelerated, and the other to Kerguelen's Island, where it is most retarded. Venus passes across these two lines like the radial arm of a protractor. The observed difference in the time of observing the phenomenon at these two stations will be about 21 minutes. Of this about 11 minutes is due to the fact that the Sandwich Islands are north of Kerguelen's Island, as before explained; the remaining 10 minutes or so will be a measure of the angle between the two lines drawn from the sun's edge to the two stations. Since Venus passes over $1''\cdot 5$ in 1 minute, 10 minutes gives us $15''$ for the effect of parallax looked at in this light.

It is a comparatively easy matter to set one's clock accurately to local time by astronomical observations. But it is a matter of considerable difficulty for an observer in Kerguelen's Island to set his clock accurately to the local time of the Sandwich Islands, or *vice versâ*. Consequently there will be some difficulty in determining the absolute difference of time of contact as observed at these two stations. The difficulty simply consists in determining the longitude accurately. This is a matter involving a long series of astronomical observations even now; still

* Histoire de l'Acad. des Sciences, p. 112.

more so in 1761. Such observations were then wanting. Hence the application of this method was not successful, and results of that transit were unsatisfactory.

Not daunted by the comparative failure of that attempt, the astronomers of last century made vigorous efforts to make the transit of 1761 successful. The transit of 1761 was utilised in so far as it pointed out the difficulties in this kind of observation and gave them an approximate value of the sun's parallax to help them in choosing the most advantageous stations from which to observe the next transit.
